Distance geometry\(^{(83–85)}\) involves taking the restraints together with the covalent structure, and creating a matrix of interatomic distances between all atoms so as to be consistent with the input. This approach is called the metric matrix distance geometry and the set of distances from $n$-dimensional space are projected into 3D Cartesian coordinate space. This method operates in distance space, whereas there are also real space methods which operate in either Cartesian coordinate space directly, or in torsion-angle space.\(^{(86)}\) The algorithm involves no initial priming with any kind of initial approximate structure. Indeed most versions start from a set of randomly generated structures with the restraints embedded. It is therefore a very unbiased way of determining structure. Mathematically, the metric matrix distance geometry approach calculates a selection of trial distances to replace the upper and lower bounds in the distance matrix $D$. The trial distances $d_{ij}$ are usually selected randomly although they must still satisfy the bounds (Equation 13):

$$ l_{ij} \leq d_{ij} \leq u_{ij} \quad (13) $$

Next the distance is calculated from each point $i$ to the center of mass, denoted as point 0, using Lagrange’s theorem (Equation 14):

$$ d_{ij}^2 = \frac{1}{N} \sum_{j=1}^{N} d_{ij}^2 + \frac{1}{N^2} \sum_{j=2}^{N} \sum_{k=1}^{j-1} d_{jk}^2 \quad (14) $$

NUCLEAR MAGNETIC RESONANCE OF BIOMOLECULES

11
The metric matrix $g_{ij}$ is defined as the scalar product of
the two vectors, $\vec{u}_i$ and $\vec{u}_j$, and can be easily calculated from
the distances using the law of cosines (Equation 15):

$$ g_{ij} = \vec{u}_i \cdot \vec{u}_j = \frac{1}{2} (d_{ij}^2 + d_{ji}^2 - d_{ij}^2) \quad (15) $$

Calculating the metric with respect to the center of mass
means that no coordinates are emphasized, and all the coordinates are comparable in magnitude. Repeating for all atom pairs yields the metric matrix $G$. The metric matrix can also be thought of as a matrix containing the projections of all atom pairs. The eigenvalues $\lambda_1, \lambda_2, \lambda_3, \ldots$ are determined and ranked according to magnitude. The three largest eigenvalues are selected and are by nature mutually orthogonal. The corresponding eigenvectors of the real symmetric metric matrix $G$ compose an $N$-column matrix $W$, where $N$ is called the embedding dimensionality and is usually three. The largest eigenvalues are chosen as the principal axes so as to minimize scatter into higher dimensions. Thus the embedded coordinates, $v_{ij}$, for point $i$ in $N$ dimensions, where $j = 1, 2, \ldots, N$ are given by Equation (16):

$$ v_{ij} = \frac{1}{\sqrt{N}} w_{ij} \quad (16) $$

One difficulty with metric matrix distance geometry is that
distances alone cannot define the chirality of the
structure, so that mirror images (local or global)
of the correct structure can occur. In general, these
can easily be rejected at the substructure stage as the
chirality of single amino acids (L) and helices (right-handed) is known. A further problem associated with
the method is that it does not sample efficiently the
conformational space consistent with the stereochemical and experimental restraints. As a result, the atomic root
mean square (RMS) distribution of a series of calculated
structures tends to be underestimated, particularly in
regions that are poorly defined by the experimental data. Subjecting these structures to restrained molecular
dynamics (RMD), for example, results in an increase in the
atomic RMS distribution, while improving the agreement with the experimental data and reducing the
van der Waals energy.

In methods involving minimization in torsion angle
space, bond lengths and angles are kept fixed during the
minimization and only the torsion angles are varied. To
ensure that correct folding occurs, the restraints have
to be introduced gradually during the calculation. This is achieved in a variety of ways, so that the distances between residues further and further apart in the sequence are incorporated in successive cycles of minimization. In general, the structures found by these methods tend to have inordinately high energies and have to be subjected to extensive energy minimization with only minimal changes in atomic RMS deviations.

### 3.4 Molecular Dynamics and Simulated Annealing

When restrained energy minimization methods are used, inevitable local energy minima are encountered which
can lead to inaccurate structures. To circumvent this, RMD are usually employed. This involves including
NMR restraints in one of the many molecular dynamics simulation programs. Molecular dynamics solves Newton’s equations of motion (Equation 17):

$$ F_i = m_i a_i \quad (17) $$

where $F_i$ is the force, $m_i$ is the mass, and $a_i$ is the
acceleration of atom $i$. The force on atom $i$ can be computed directly from the derivative of the potential energy $V$ with respect to the coordinates $r_i$. The energy can be expressed in the explicitly differentiable form of Equation (18):

$$ -\frac{dV}{dr_i} = m_i \frac{d^2r_i}{dt^2} \quad (18) $$

Therefore, with an adequate expression for the potential energy and known masses, this differential equation
can be solved for future positions in time, $t$. In general, this can be solved only approximately, as $V$ is
usually a complex function of the coordinates of all (or many) of the atoms (i.e. $V = V(r_1, r_2, r_3 \ldots r_N)$). The temperature can be calculated from the atomic velocities (Equation 19),

$$ \frac{3N}{2} k_B T = \sum_{i=1}^{N} \frac{1}{2} m_i v_i^2 \quad (19) $$

where $k_B$ is Boltzmann’s constant, $m_i$ and $v_i$ are the
mass and velocity of atom $i$, and $N$ is the number of atoms (and $3N$ is the number of degrees of freedom). For a simulation at constant energy, the temperature fluctuates
due to the interconversion of kinetic and potential energy. If the temperature is held constant, then the atomic velocities can be adjusted accordingly. If the pressure is held constant, the volume must be allowed to fluctuate by rescaling the interatomic distances. The total potential energy, $V_{\text{total}}$, is usually defined (Equation 20) as the sum of a number of terms:

$$ V_{\text{total}} = V_{\text{bond}} + V_{\text{angle}} + V_{\text{dihedr}} + V_{\text{vdW}} + V_{\text{coulomb}} + V_{\text{NMR}} \quad (20) $$

where $V_{\text{bond}}, V_{\text{angle}}$, and $V_{\text{dihedr}}$ keep bond lengths, angles and dihedral angles at their equilibrium values. (The first five terms are empirical energy terms describing the physical interactions between the atoms, whereas the last term is a means of including the NMR information, but does not correspond to any real physical force.) They are
summarized in Equations (21–23):

\[
V_{\text{bond}} = \sum_{\text{bonds}} \left( \frac{1}{2}K_b(b - b_0)^2 \right) \tag{21}
\]

\[
V_{\text{angle}} = \sum_{\text{angles}} \left( \frac{1}{2}K_{\theta}(\theta - \theta_0)^2 \right) \tag{22}
\]

\[
V_{\text{dihedr}} = \sum_{\text{dihedr}} K_\phi [1 + \cos(n\phi - \delta)] \tag{23}
\]

These are pseudoharmonic potentials that constrain bond lengths (\(b\)), bond angles (\(\theta\)), and the rotamer angles (\(\phi\), \(\delta\)) for staggered and eclipsed conformations, and \(K\) is a constant. The van der Waals and electrostatic interactions are described by \(V_{vdW}\) and \(V_{\text{coulomb}}\):

\[
V_{vdW} = \sum_{\text{pairs} (ij)} \frac{C_{12}}{r_{ij}^{12}} - \frac{C_6}{r_{ij}^6} \tag{24}
\]

\[
V_{\text{coulomb}} = \sum_{\text{pairs} (ij)} \frac{q_i q_j}{4\pi\varepsilon_0\varepsilon_r r_{ij}} \tag{25}
\]

where Equation (24) is the Lennard–Jones potential, containing repulsive and attractive terms (\(C\) is a constant), and Equation (25) describes the coulombic interactions between two charged particles (\(i, j\)) with partial charges \(q\) that are a distance \(r_{ij}\) apart in a dielectric medium described by \(\varepsilon_0\varepsilon_r\). The term \(V_{\text{NMR}}\) contains the NMR restraints, and has the effect of pulling the protons that show an NOE interaction closer to the measured distance \(r_{ij}\). Similarly, \(V_{\text{NMR}}\) may also contain J-coupling information by including a torsion term. These potentials are also pseudo harmonic functions of similar form to Equations (21–23). Distance constraints which can be reasonably accurately determined may therefore be defined as Equation (26):

\[
V_{\text{NOE}} = \begin{cases} K_1(r_{ij} - r_{ij}^0)^2 & \text{if } r_{ij} > r_{ij}^0 \\ K_2(r_{ij} - r_{ij}^0)^2 & \text{if } r_{ij} < r_{ij}^0 \end{cases} \tag{26}
\]

where \(r_{ij}\) and \(r_{ij}^0\) are the calculated and experimental interproton distances respectively, and \(K_1\) and \(K_2\) are force constants given by Equation (27):

\[
K_1 = \frac{k_B TS}{2(\Delta q^+_i)^2} \quad \text{and} \quad K_2 = \frac{k_B TS}{2(\Delta q^-_i)^2} \tag{27}
\]

where \(k_B\) is Boltzmann’s constant, \(T\) is the absolute temperature of the simulation (\(\text{not}\) the experiment), \(S\) is a scale factor, and \(\Delta q^+_i\) and \(\Delta q^-_i\) are the positive and negative error estimates, respectively, of \(r_{ij}\). If, however, only ranges of distances can be specified, then the distance restraints are incorporated into a pseudo square-well potential (Equation 28):

\[
V_{\text{NOE}} = \begin{cases} K_{\text{NOE}}(r_{ij} - r_{ij}^0)^2 & \text{if } r_{ij} > r_{ij}^0 \\ 0 & \text{if } r_{ij}^0 \leq r_{ij} \leq r_{ij}^0 \end{cases} \tag{28}
\]

\[
K_{\text{NOE}}(r_{ij} - r_{ij}^0)^2 \tag{28}
\]

where \(r_{ij}^0\) and \(r_{ij}\) are the upper and lower limits, respectively, of the target distances obtained from experiment, and \(K_{\text{NOE}}\) is the NOE force constant, which is typically chosen to be of the order of 1000 kJ mol\(^{-1}\) nm\(^{-2}\). Similarly, torsion angle restraints can be incorporated into pseudo square-well potentials (Equation 29):

\[
V_{\text{tor}} = \begin{cases} K_{\text{tor}}(\phi_i - \phi_i^u)^2 & \text{if } \phi_i > \phi_i^u \\ 0 & \text{if } \phi_i^u \leq \phi_i \leq \phi_i^v \\ K_{\text{tor}}(\phi_i - \phi_i^v)^2 & \text{if } \phi_i < \phi_i^v \end{cases} \tag{29}
\]

where \(\phi_i^u\) and \(\phi_i^v\) are the upper and lower limits of the target range of a particular torsion angle obtained from experiment, \(\phi_i\) is its calculated value, and \(K_{\text{tor}}\) is the torsion force constant, which is typically chosen to be of the order of 4000 kJ mol\(^{-1}\) rad\(^{-2}\). To ensure that the experimental restraints are the dominating factor in determining the conformation of the molecule, it is very important that the force constants for the restraints are set sufficiently high that the experimental data are satisfied within the precision of the measurements. At the same time, the contribution from the empirical energy function should be such that for any individual RMD structure the deviations from ideal geometry are small, and the nonbonded interactions are good (i.e. the Lennard–Jones potential is negative). This can be determined from a few trial calculations. Thus, convergence on the structure is guided by the requirement to minimize NOE or other restraint violations. The number of distance restraint violations \(N_{\text{viol}}\) is counted when, for example, \(r_{ij} \geq r_{ij}^0 + 1\), which would allow for 1 Å fluctuations. Another parameter that can be minimized in addition to \(N_{\text{viol}}\) is the sum of the distances in excess of the constraints \(\Delta r_{\text{viol}}\), as given by Equation (30):

\[
\sum_{k=1}^{N_{\text{viol}}} \Delta r_{\text{viol}} = \sum_{k=1}^{N_{\text{viol}}} (r_{ij})_k - [(r_{ij}^0)_k + 1] \tag{30}
\]
methods. This problem can be overcome by using a simplified potential energy function, where all nonbonded contact interactions are described by a single van der Waals repulsion term. Also, by using a cut-off distance, in which nonbonded interactions for pairs of atoms that are separated by a distance greater than some reasonable value (e.g. 5–10 Å), the number of nonbonded interactions is decreased significantly.

Simulated annealing involves raising the temperature of the system followed by slow cooling in order to overcome local minima and locate the global minimum region of the target function. It is computationally more efficient than RMD and yields structures of similar quality. The potentials are very similar to RMD and again Newton’s laws of motion are solved as a function of time. However, in implementations found in commercial programs, the nonbonded interaction potential is modified so that there is a simple van der Waals repulsion term with a variable force constant $K_{\text{rep}}$ (Equation 31):

$$V_{\text{repel}} = \begin{cases} 0 & \text{if } r \geq s r_{\text{min}} \\ K_{\text{rep}} (s^2 r_{\text{min}}^2 - r^2)^2 & \text{if } r < s r_{\text{min}} \end{cases} \quad (31)$$

The values of $r_{\text{min}}$ are given by the sum of the standard values of the van der Waals radii between two atoms as represented by the Lennard–Jones potential used in, for example, the empirical energy function CHARMM (Chemistry at Harvard Molecular Mechanics). A van de Waals scale factor, $s$, typically should be set to 0.8 to account for the fact that interatomic separations slightly smaller than the sum of the hard-sphere van der Waals radii can easily occur due to the attractive component of the van der Waals interaction. Further potentials and force constants can be introduced for refinement against chemical shift and torsion angle databases, and for inclusion of residual dipolar couplings.

### 3.5 Energy Minimization

The next step in biomolecular structure determination is the refinement of the distance geometry-derived Cartesian coordinates. Energy minimization is generally used to find local minima in the potential energy for the structure. Commonly employed energy minimization algorithms offer choices of one of the following methods: steepest descent, conjugate gradient (also known as Powell), and Newton–Raphson. All these assume that the energy surface is approximately harmonic, and physically adjust the atomic positions in Cartesian space over the energy surface, deeper into the local potential well. Although the rate of descent for the steepest descent method is initially fast, it is nonconvergent and often results in large oscillations about the minimum. This may lead to structures that have climbed out of the local well to a higher energy point. The conjugate gradient method approaches the minimum more slowly, and results in a converged minimum point energy. However, for very poor starting structures, it is more likely to converge.

In general, for biomolecules, 100 or so steps of steepest descent minimization are followed by 500–1000 steps of either conjugate gradient or modified Newton–Raphson methods. These energy minimization steps can be carried out at a variety of the steps involved in generating NMR structures of biomolecules. Restraints can be included in some of the implementations of these algorithms. In fact, too many minimization steps without restraints (and without including solvent molecules) may lead to structures that are far from either X-ray crystal or NMR structures. Therefore, although these methods are used to generate theoretical model structures, without restraints, their indiscriminate application to biological problems is likely to lead to meaningless structures that are not at all helpful in understanding their function.

---

**Figure 6** The strategy for solving the 3D structure of biomolecules on the basis of NMR data. (Adapted from ref. 8 with permission.)
3.6 Procedure for Structure Determination

The typical procedure in obtaining an NMR structure is as follows. The NMR spectra are assigned using 2D, 3D, and 4D NMR experiments, and from these a list of distance restraints derived from NOEs and/or dipolar couplings are generated, together with torsion angle restraints derived from J couplings and/or dipolar couplings. This list is used to determine a set of NMR force potentials that, together with a seed of randomly generated initial extended chain structures, form the input files for distance geometry and/or RMD/simulated annealing calculations (Figure 6).

When the structures converge on a well-defined structure (the next section provides a definition of "well-defined"), then either the whole family of structures or a calculated average structure can be subjected to further restrained dynamics or energy minimization, to generate the final structures. Generally it is preferable to keep the whole family of structures, and submit them to the Protein Data Bank as the final structure. Such families inform users of the structural data as to the areas of the structure that are not well-defined. However, if the structures do not converge, then a sometimes lengthy iteration of going back to the original data to check assignments (both in terms of chemical shifts and NOE intensities) and recalculation of structures ensues. This can be supplemented with use of iterative relaxation matrix approaches to back-calculate the NOESY spectra, and comparison with the experimental data can lead to a semi-automated way of recalculating the structures. This method seems to work for relatively small molecules, but generally fails in biomolecules whose Mᵢ exceeds 15 kDa. Refinement of the structure continues until some criteria of accuracy are met.

3.7 Assessing the Accuracy and Precision of the Final Structure

As already discussed, the typical procedure for obtaining NMR structures involves using a large number of different starting structures for the distance geometry and/or RMD/simulated annealing. If a significant fraction of the calculated structures converge, satisfying all the NMR restraints, and show a root-mean-square deviation (RMSD) from each other of less than 2 Å, then this indicates that the calculated structures must be close to the actual structure. The RMSD is generated by superimposing the centroids of the structures, and calculating a rotation that minimizes the overall value (Equation 32):

\[
\text{RMSD} = \frac{1}{N} \sum_{i=1}^{N} (r_i - r'_i)^2
\]

where N is the number of atoms being compared, and rᵢ and r'ᵢ are the atomic coordinates for the standard structure and the rotated structure, respectively. For comparisons of families of NMR structures, each of the structures is rotated so as to provide the best fit with a predetermined member of the family. The RMSD values are reported for all pairwise structure comparisons. If serious violations of the NMR restraints remain, or if the RMSD between the various structures is too large, then reanalysis of the NMR spectra is necessary. A further check can be made using the iterative relaxation matrix approach and back-calculating the NOESY spectrum from the structure. The precision of the measurements, for example how narrowly the bounds for NOE-derived distances are defined, will improve the RMSD between the set of calculated structures and therefore the accuracy of the structure. Those NMR protein structures that show a relatively low level of detail typically have RMSDs of at least 1.5–2 Å. Higher-resolution structures show RMSDs of the order of 0.8 Å for the backbone atoms, 1 Å for backbone atoms plus some interior side-chain atoms, and around 1.5 Å for all the atoms in the molecule. Such improvements in resolution can be attributed in part to the availability of stereospecific assignments, which have the effect of narrowing the distance bounds. Relatively few restraints are sufficient to define the global fold in proteins, whereas the same is not true for nucleic acids, where there are no possible long-range constraints. Here iterative relaxation matrix approaches to refinement of the precision of the distance measurements from NOESY cross-peak volumes is very important.

Another method that is beginning to be used in assessing the accuracy of a structure is the R factor, or structure factor, which, by analogy with the term in X-ray crystallography, is the normalized mean deviation between the structure factors derived from the model and the experimental data. For NMR data, this usually involves a direct measure of the fit between the experimental and theoretical NOE intensities when the final model is subjected to back-calculation of the NOESY spectrum. In its simplest, most general form the NMR R factor is defined as in Equation (33):

\[
R = \frac{\sum_{i,j} W_{ij}(\tau_m) A_{ij}^{\text{calc}}(\tau_m) - A_{ij}^{\text{exp}}(\tau_m)}{\sum_{i,j} W_{ij}(\tau_m) A_{ij}^{\text{exp}}(\tau_m)}
\]  

(33)

where \(A_{ij}^{\text{calc}}(\tau_m)\) and \(A_{ij}^{\text{exp}}(\tau_m)\) are the elements connecting protons i and j of the theoretical and experimental NOE intensity matrices for a given mixing time \(\tau_m\). Weight factors \(W_{ij}(\tau_m)\) are included to account for measurement errors. A number of other definitions of the R factor have appeared, and some of the available algorithms calculate...
several different types of \( R \) factor simultaneously. The convergence limit on as low an \( R \) factor as achievable in an iterative relaxation matrix structure calculation is usually used as the stopping point for the refinement. However, as for X-ray crystallography, the \( R \) factor only measures the agreement of the calculated structure with the experimental data, so that a low value does not necessarily mean an accurate structure if the precision of the measurements is poor. One type of \( R \) factor recently introduced\(^{195}\) that attempts to circumvent this problem relies on cross-validation, which is a statistical method that estimates the quality of the fit to the observed data without making any assumptions about the distribution of errors in the NMR data.

Despite best efforts at obtaining precise distance measurements for use in calculating accurate structures, there are often still regions of a molecular structure for which NMR restraints are absent. These regions are therefore disordered during all the refinement procedures, and it is tempting to suggest that this region has considerable conformational flexibility. In other words, a common argument is that absence of NOEs for example) is not sufficient to establish that a structure is disordered and conformationally labile. This can be addressed by measuring backbone dynamics using \(^{15}\)N-labeled protein and measuring heteronuclear \(^{15}\)N \( T_1 \), \( T_{1p} \), and \( T_2 \) relaxation rates and \(^1\)H–\(^{15}\)N NOEs, so that the order parameter \((S^2)\) can be calculated.\(^{96–99}\) This is a more rigorous way of determining whether molecular motion is the real reason for the absence of NOEs. Similarly, side-chain dynamics can be probed using measurements of \(^{13}\)C \( T_1 \), \( T_{1p} \), and \( T_2 \) relaxation rates and \(^1\)H–\(^{13}\)C NOEs and \(^2\)H \( T_1 \) and \( T_{1p} \) relaxation rates.\(^{100,101}\)

### 4 OBTAINING LONG-RANGE DISTANCE AND ANGLE INFORMATION

The need for a long-range distance and angle information is clear when liquid-state NMR is only capable of furnishing distances of the order of 5 Å, and angle information for spins involved in direct scalar \( J \)-coupling interactions. Here a number of approaches are emerging that have the potential to address this significant shortcoming of NMR as a biomolecular structural technique.

#### 4.1 Use of Shift Tensors to Obtain Torsion Angles

The origin of the chemical shift is that the moving electric charges of the electron cloud around a nucleus induces a local magnetic field which opposes the applied field. Thus the effective field at the nucleus is (Equation 34):

\[
B_{\text{eff}} = B_0(1 - \sigma_{\text{iso}})
\]

The nucleus is said to be shielded, and the extent of the shielding is given by the shielding constant, also called the isotropic chemical shift tensor, \( \sigma_{\text{iso}} \). This is directly related to the electron density \( \rho \) at a distance \( r \) from the nucleus by Lamb’s equation (Equation 35):

\[
\sigma_{\text{iso}} = \frac{4 \pi e^2}{3 mc^2} \int_{-\infty}^{\infty} \rho(r) \, dr
\]

There are three principal components of the shift tensor, \( \sigma_{11}, \sigma_{22} \) and \( \sigma_{33} \), and the isotropic shift tensor \( \sigma_{\text{iso}} \) is given by Equation (36):

\[
\sigma_{\text{iso}} = \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33})
\]

The shift tensor \( \sigma_{\text{iso}} \) is related to the Larmor frequency \( \nu_0 \) by Equation (37):

\[
\nu_0 = \frac{\gamma}{2 \pi} B_0(1 - \sigma_{\text{iso}})
\]

and to the chemical shift by Equation (38):

\[
\delta = 10^6(\sigma_{\text{ref}} - \sigma_{\text{sample}})
\]

By appropriate choice of a coordinate system, the isotropic chemical shift \( \sigma_{\text{iso}} \), which is a \( 3 \times 3 \) matrix, or second rank tensor, may be converted to three principal elements, \( \sigma_{11}, \sigma_{22} \) and \( \sigma_{33} \), which serve to characterize the 3D nature of the shielding. From these elements it is possible to define the shielding anisotropy \( \Delta \sigma \) and the shielding asymmetry parameter \( \eta \) (Equations 39 and 40):

\[
\Delta \sigma = \sigma_{33} - \frac{1}{2}(\sigma_{11} + \sigma_{22})
\]

\[
\eta = \frac{\sigma_{22} - \sigma_{11}}{\sigma_{33} - \sigma_{\text{iso}}}
\]

The chemical shielding tensor ellipsoid is illustrated in Figure 7, together with the relationship between the principal axis system and the laboratory frame (the frame in which \( B_0 \) resides). The principal elements of the shift tensor can be obtained by rotational side-band intensity analysis.\(^{102}\) The parameter \( \Delta \sigma \) provides an estimate of the departure from spherical symmetry of the electrons around the nucleus.

In solution, the isotropic molecular motion averages the shift anisotropy (see Equation 36), except in cases where there is partial ordering of the sample. In the solid state, the chemical shift anisotropy will be manifested according to the state of the sample:
4.2 Use of Residual Dipolar Couplings to Obtain Distance and Angle Restraints

Distance and angle information can be obtained from NMR through the determination of dipolar couplings. The dipole–dipole interaction is averaged to zero in an isotropically tumbling liquid. However, for a biological macromolecule, tumbling can be anisotropic under conditions of high magnetic fields or in the presence of a liquid crystalline phase. These methods partially orient the liquid-state sample through the use of lipid bicelles, filamentous phage, viruses, or purple membranes. Under these circumstances, residual dipolar couplings can be measured, which can give restraints relative to a molecular frame, enabling domains to be oriented relative to one another, and leading to more accurate distance measurements. They can be measured using pulse sequences which measure the contribution to J couplings that are due to residual dipolar couplings, such as the in-phase/antiphase (IPAP) HSQC and HNCO pulse sequences. Such residual dipolar couplings can then be incorporated into simulated annealing protocols for structure refinement, using Equation (41) for dipolar couplings between two nuclei, P and Q, relative to the molecular alignment tensor:

\[ D_{PQ}(\theta, \phi) = S \frac{h }{ 4\pi \gamma_P \gamma_Q \gamma_h} \frac{3}{2} A_1 \sin^2 \theta \cos 2\phi \]

where \( S \) is the generalized order parameter for internal motion of the PQ vector, \( \gamma_P \) and \( \gamma_Q \) are the gyromagnetic ratios of P and Q, \( h \) is Planck’s constant, \( r_{PQ} \) is the distance between P and Q, and \( \theta \) and \( \phi \) are the cylindrical coordinates describing the orientation of the PQ vector in the principal axis system of A. Values for the axial (\( A_3 \)) and rhombic (\( A_2 \)) components of A depend on the shape of the protein and vary with the bicelle concentration. These approaches are already having a significant impact on NMR structure determination, and are likely to revolutionize liquid-state biomolecular structure determination in general. However, there still remains the need for accurate distance measurements in larger macromolecular assemblies, or in unoriented soluble proteins whose molecular weight exceeds the current liquid-state NMR limits, and here solid-state NMR has a lot to offer.

4.3 Solid-state Nuclear Magnetic Resonance in Biomolecular Structure Determination

As the dipolar coupling is not averaged to zero in the solid state, it can be a valuable source of distance information from NMR in addition to NOEs. Torsion angles can also be determined very accurately from the angular dependence of the dipolar coupling, and can be used to determine the structure of a small biomolecule. Distances and torsion angles calculated from the measured dipolar coupling constant in the solid

---

**Figure 7** The chemical shielding ellipsoid, which is used to indicate that different orientations of the magnetic field relative to the molecular framework result in different resonance positions for the same chemical species. (Adapted from ref. 8 with permission.)
4.3.1 Homonuclear Dipolar Recoupling to Obtain Distances

Most modern solid-state NMR approaches reduce linewidths which are broadened by large proton–proton dipolar couplings by use of magic-angle spinning (MAS). This technique causes all the dipolar couplings (both homonuclear and heteronuclear) in the dipolar Hamiltonian to fluctuate sinusoidally during the rotor cycle, so that integrating the Hamiltonian over one rotor cycle gives zero. A number of methods have been introduced recently which selectively reintroduce the dipolar coupling (hence “recoupling”) for strongly coupled homonuclear spins and use this to measure selected distances in biomolecules, particularly those with $M_r > 50000$. Almost all the techniques work by manipulating the dipolar Hamiltonian in such a way that it integrates to a nonzero value over the rotor cycle, scaled by a factor determined by the particular experiment. The first technique, called rotational resonance (or R²), introduced by Griffin et al. relies on the fact that magnetization transfer between two homonuclear spins is most efficient when the chemical shift difference equals an integral of the MAS frequency, which can place the spinning side-band of one resonance overlapping with the isotropic resonance of another. This phenomenon is called the rotational resonance condition, and is given by Equation (42),

$$\Delta v = n\nu_r$$  \hspace{1cm} (42)

where $\Delta v$ is the chemical shift difference of the cross-relaxing resonances, $n$ is an integer, and $\nu_r$ is the spinning speed. Clearly the requirement for isotropic resonances to be well separated places some restrictions on the applicability of this method. Griffin et al. made use of this phenomenon using isotopic labels, although others have used it at natural abundance. The pulse sequence (Figure 8) involves an exchange time for magnetization transfer to occur. If the two rotationally coupled spins are also close in space, and therefore dipolar recoupled, their resonance intensities will vary as a function of the mixing time due to a transfer of magnetization. When spinning at the $n = 1$ rotational resonance condition, the initial rate of magnetization transfer is dominated by the strength of the dipolar coupling. As the value of $n$ increases, the rate of transfer decreases and contributions from the orientations of the chemical-shift tensors become more significant, making interpretation of the transfer rate more difficult. Therefore the $n = 1$ experiments are the most useful, although it is still necessary to know the isotropic shifts of the two resonances, the zero quantum transverse decay $T_2^{ZQ}$, the principal values of the shift tensors (which are known for many functional groups) and, less important, the mutual orientation of the two tensors. The zero-quantum $T_2^{ZQ}$ decay influences magnetization transfer, because the difference polarization is continuously exchanged with zero quantum coherence under the influence of dipolar coupling, and may be measured from Hahn spin–echo experiment. Theoretical simulations of strongly coupled sites also predict $T_2^{ZQ}$ and oscillations in the transfer curves that result from the relative orientations of the exchanging sites.

As the magnetization transfer is proportional to the dipolar coupling ($D$), measurement of $D$ can be used to calculate internuclear distance $r$ according to Equation (43):
NUCLEAR MAGNETIC RESONANCE OF BIOMOLECULES

where $\gamma_1$ and $\gamma_5$ are the gyromagnetic ratios for the two spins involved (in the case of the $R^2$ experiment, this means two homonuclear spins, so $\gamma_1 = \gamma_5$, although obviously this can apply to two heteronuclear spins), $h$ is Planck’s constant divided by $2\pi$, and $\mu_0$ is the permittivity of a vacuum. The experimental data fit with simulated curves to an accuracy of $\pm 0.4$ Å for an isolated spin pair (e.g. $^{13}C$–$^{13}C$ or $^{31}P$–$^{31}P$), and the limits of distances which may be detected can be as high as 18 Å for $^{19}F$–$^{19}F$ pairs. These distances can be used as restraints in distance geometry and/or simulated annealing calculations.

A number of other homonuclear recoupling methods have been introduced, including RFDR (rotor-driven dipolar recoupling), DRAMA (dipolar recovery at the magic angle) and its variants, MELODrama (melding of spin-locking and DRAMA), DRAWS (dipolar recoupling with a windowless sequence), CROWN (combined rotation with nutation), HORROR (homonuclear rotational resonance), C7 (7-fold symmetric homonuclear recoupling), and POST-C7 (compensated 7-fold symmetric homonuclear recoupling).

4.3.2 Homonuclear Dipolar Recoupling to Obtain Angles

The rotational resonance experiment can also be used to measure torsion angles. At higher orders of the rotational resonance condition, $n \geq 3$, the magnetization exchange rate is not only dependent on the internuclear distances but also very strongly dependent upon the relative orientation of the two chemical shift tensors (provided they are both large). McDermott et al. have used this approach to measure dihedral angles between two adjacent nonprotonated carbons in phosphoglycolate bound to triosephosphate isomerase, to an accuracy of $\pm 0.5^\circ$. They made use of the fact that the intensity of the zero quantum side-bands depends systematically on the dihedral angle, which can be measured by determining the magnetization exchange rates at $n = 4$.

There are alternative approaches to $R^2$ for mutually orienting two homonuclear shift tensors, and thereby obtaining torsion angles. There are also new techniques emerging for orienting the chemical shift tensors of two dipolar coupled spins with respect to one another, using magnetization transfer, including rotational resonance, or multiple quantum coherence, including C7.

4.3.3 Heteronuclear Dipolar Recoupling to Obtain Distances

The principal heteronuclear technique introduced by Schaefer et al. is called rotational echo double resonance (REDOR), and relies on the dephasing of magnetization of one spin in the presence and absence of dipolar coupling to another heteronucleus, and subsequent refocusing as a function of the MAS frequency. The variation of intensity for the one nucleus in the presence and absence of dephasing of the other nucleus is directly proportional to the dipolar coupling constant. The pulse sequence is outlined in Figure 9.

Figure 9 Pulse sequence for a version of REDOR $^{13}C$-NMR. Two equally spaced $180^\circ$ $^{15}N$ pulses per rotor period result in dephasing of transverse carbon magnetization produced by cross-polarization (CP) transfer from dipolar-coupled protons. The $180^\circ$ $^{13}C$ pulse replaces the $^{13}N$ pulse in the middle of the dephasing period and refocuses isotropic $^{13}C$ chemical shift differences at the beginning of data acquisition. High power $^1H$-decoupling is maintained throughout the $^{15}N$ dephasing sequence and the acquisition. (Adapted from ref. 8 with permission.)

The first spectrum is obtained using a standard cross-polarization pulse sequence with a $\pi$ pulse on the observed nucleus (e.g. $^{13}C$) in the middle of the evolution period. During this period, the observable magnetization evolves under the influence of the chemical shifts and the heteronuclear dipolar interaction. The $180^\circ$ pulse refocuses both interactions, leading to a signal $S$ during the acquisition period. The second spectrum is obtained with an additional train of $\pi$ pulses on the dipolar-coupled spin (e.g. $^{15}N$). These pulses affect the observed signal by preventing rotational refocusing of the dipolar interaction. The magnetization is therefore not completely refocused, and the signal intensity drops by an amount $\Delta S$. For weak dipolar coupling, the change in signal intensity is related to the distance between the coupled spins by Equation (44)

$$\frac{\Delta S}{S} = KD^2N_c^2v_r^{-2}$$

where $N_c$ is the number of rotor cycles during the evolution period, $v_r$ is the spinning speed, $D$ is the...
dipolar coupling, and $K$ is a dimensionless constant. If performed at relatively slow spinning speeds and over several rotor cycles, the size of the difference signal can be increased. This experiment therefore yields the internuclear distance, which for an isolated spin pair (e.g. $^{13}\text{C} -$ $^{15}\text{N}$ or $^{31}\text{P} -$ $^{13}\text{C}$) can be determined to an accuracy of around $\pm 0.1 \text{ Å}$.

One advantage this experiment has over the current homonuclear methods is that a universal curve can be used for the calculation of distances. There is no dependence on the values or orientations of the chemical shift tensors, or on the zero-quantum $T_2^Q$. Therefore once a particular instrument has been calibrated with a known sample, such a curve can be used to read off dipolar couplings directly. Furthermore, the distances that can be measured can be quite considerable, for example $< 5 \text{ Å}$ for $^{13}\text{C} -$ $^{15}\text{N}$, $< 8 \text{ Å}$ for $^{13}\text{C} -$ $^{31}\text{P}$, and $< 12 \text{ Å}$ for $^{13}\text{C} -$ $^{19}\text{F}$. Also REDOR can be applied$^{148-153}$ to quadrupolar nuclei, for example $^2\text{H}$ and $^{14}\text{N}$.

Other variants of REDOR include experiments involving three or more $S$ spins, such as the transferred-echo double resonance (TEDOR) experiment,$^{154}$ which can be used to edit out the natural abundance background signals by selecting unique spin triplets. A third rare spin, such as $^2\text{H}$, $^{19}\text{F}$, or $^{31}\text{P}$, is used to distinguish the signal arising from a specific $^{13}\text{C} -$ $^{15}\text{N}$ pair from that of the natural abundance background, although they require specialized quadrupole resonance instrumental capabilities. Another interesting development has been the application by Mueller et al.$^{155,156}$ of a Bessel function transform to deconvolute multiple time-dependent dephasing signals, and thereby measure multiple dipolar couplings simultaneously.$^{157}$

The REDOR technique has been further developed, including the REDOR/TOSS (total side-band suppression) pulse sequence,$^{158,159}$ alternative phase-cycling schemes,$^{160-164}$ and more recently the REDOR/TPPM (two-pulse phase modulation) pulse sequence.$^{165}$ Finally, the approach called REDOR-editing$^{166}$ can be used to edit a spectrum with a large natural abundance background with respect to a dipolar coupled spin pair that are unique to a biological molecule.

**4.3.4 Heteronuclear Dipolar Recoupling to Obtain Angles**

This method was developed by Opella, Cross et al., and determines the torsion angles, for example in the polypeptide backbone of a protein, as a means to determine structure based solely on orientational restraints.$^{167-169}$ We will consider the theory of this technique as applied to proteins. Although it could be applied to other classes of biomolecules such as DNA, to date its use has been limited primarily to membrane proteins.

The $\alpha$ carbons of adjacent amino acids in a polypeptide chain are joined by the amide $\text{C} -$ $\text{N}$ bonds. The six atoms that form this peptide linkage lie roughly in a plane, and the relative orientation of adjacent planes is defined by the $\phi$ and $\psi$ torsion angles (see Figure 10). The secondary structure of the peptide backbone can be determined by establishing the sequential orientation of each peptide plane relative to a common axis.

Measurements of both the dipolar and chemical shift interactions are necessary to limit the number of possible orientations and define the peptide structure.$^{167,169-171}$

The orientation dependence of the dipolar interaction is given by Equation (45):

$$\Delta v = D (3 \cos^2 \theta - 1)$$

where $\Delta v$ is the observed dipolar splitting, $D$ is the dipolar coupling constant, and $\theta$ is the angle between the internuclear vector connecting the spins and the external magnetic field. The dipolar interactions point along the bond axes and are axially symmetric. The observed dipolar splitting ranges from zero for bonds aligned at the magic angle, to $2D$ for bonds parallel to the $z$ axis of the magnetic field. One of the problems in determining peptide plane orientations is that the experimental $\Delta v$ specifies two or four different values for $\theta$ depending on the size of $D$ relative to $\Delta v$. Consequently, several bond orientations need to be measured to arrive at a unique solution for the peptide-plane orientation. The $^{15}\text{N} -$ $^1\text{H}$ and $^{15}\text{N} -$ $^{13}\text{C}$ bond orientations are the most readily measured dipolar interactions because they involve spin-1/2 nuclei, although $^{14}\text{N}$ quadrupole and dipole splittings can also be measured and used as orientation restraints.$^{172,173}$

Additional restraints for peptide-plane orientations can be derived from the amide $^{15}\text{N}$ and carbonyl $^{13}\text{C}$ chemical-shift tensors. The orientation dependence of the chemical

![Figure 10 Illustration of the peptide planes of a dipeptide and the appropriate orientations of the amide $^{15}\text{N}$ and carbonyl $^{13}\text{C}$ chemical shift tensors with respect to the molecular frame. The $\phi$ and $\psi$ angles define the orientation of the planar peptide linkages and are determined by measuring the $\text{N} -$ $\text{C}$ and $\text{N} -$ $\text{H}$ bond orientations, as well as the orientation of the $^{15}\text{N}$ and $^{13}\text{C}$ shift tensors. (Reprinted from ref. 103 with permission.)](image-url)
shift interaction is given by Equation (46):

\[
\sigma = \sigma_{11} \cos^2 \alpha \sin^2 \beta + \sigma_{22} \sin^2 \alpha \cos^2 \beta + \sigma_{33} \cos^2 \beta
\]  

(46)

where \( \sigma \) is the observed chemical shift, \( \sigma_{11}, \sigma_{22}, \) and \( \sigma_{33} \) are the principal components of the chemical shift tensor, and \( \alpha \) and \( \beta \) are the Euler angles relating the principal axis system of the chemical-shift tensor to the laboratory frame (Figure 7). Although the dipolar interaction points along the internuclear axis and is related to the magnetic field axis by a single rotation about an angle \( \theta \), the orientation of the chemical-shift tensor must be determined relative to a molecular axis and relative to the magnetic field axis. The standard approach for establishing the orientation of a chemical-shift tensor relative to a molecular axis system has been through NMR studies of single crystals in which the molecular axis orientation can be determined independently using X-ray methods. More recent methods have been developed that make use of the axial orientation of dipolar interactions as a convenient frame of reference.

**5 EXAMPLES OF BIOMOLECULAR NUCLEAR MAGNETIC RESONANCE**

There are essentially limitless ways that NMR spectroscopy can be and has been applied to the study of biomolecules. Rather than attempting to provide an exhaustive treatment here (which has been covered more fully elsewhere), this section highlights a few examples to illustrate the use of NMR to study proteins, nucleic acids and enzymes, and one elegant example from the literature of a membrane protein structure determination.

**5.1 Proteins and Nucleic Acids**

A brief example of the ways in which NMR can be applied to the structure determination of a protein–DNA complex is recent work on the high-mobility group (HMG) I/Y protein. Using high-resolution multinuclear multidimensional solution-state NMR spectroscopy, the structure of the protein–DNA complex of the HMG I/Y protein complexed to a 12-mer oligonucleotide was determined. This protein is relatively small (\( M_r = 11 \) kDa, 107 residues), so at first sight would be amenable to standard \(^1\)H-NMR COSY and NOESY approaches outlined in section 2.3.1. However this protein turns out to be unusual in that, in the absence of DNA, the protein is largely unstructured, and contains a large number of lysine, arginine, and proline residues, making assignments difficult. In the presence of DNA, the protein becomes partially structured, and binds largely to the minor groove of DNA, although it still remains a difficult assignment problem, particularly when complexed to 12-mer DNA. Therefore it was necessary to generate \(^{13}\)C-\(^{15}\)N-labeled protein truncated to contain two of the three DNA-binding domains (DBDs) (Figure 11). A large number of standard 3D NMR experiments were carried out on the protein complexed with 12-mer DNA (Table 1).

Representative strip plots from 3D CBCANH and CBCA(CO)NH spectra are shown in Figure 12. Use

of $^{13}$C-separated, $^{12}$C-filtered, and $^{15}$N-separated, $^{12}$C-filtered NOESY experiments has enabled identification of over 100 intermolecular NOE contacts between the protein and the DNA (Figure 13). These experiments rely on the ability to select either the species that is isotopically labeled, or the species that is not, as illustrated in Figure 14. Using $^{12}$C/$^{12}$C-filtered NOESY experiments the DNA spectrum was assigned. A representative region is shown in Figure 15. One discovery with this sample was that only one HMG-I(Y) DBD was bound to the 12-mer DNA operator at any one time, with a difference between the two bonding affinities for the two DBDs in the truncated protein used for the structure determination. The structures of each DBD bound to DNA have been determined, as illustrated in Figure 16. A summary of the structural statistics is given in Table 2. Note that the region between the two DBDs is involved in protein–protein interactions, but because the DNA operator used in this structure determination was too short, no structural information could be obtained for this region.

---

**Figure 13** Summary of the DNA contacts involving DBD2 and DBD3. The DNA is represented as a cylindrical projection viewed from the minor groove side. Bases are indicated as thick lines, the deoxyribose sugar rings as pentagons, and the phosphates as circles. Contacts involving amino acid side-chains and backbone amides are indicated by solid and dashed arrows, respectively. (Adapted from ref. 181 with permission.)
5.2 Enzymes

In addition to NMR being useful in determining protein structure, it can be used to probe functionally critical regions of proteins, such as encountered in the active site of an enzyme. An example of this is work on the enzyme 5-enolpyruvyl-shikimate-3-phosphate (EPSP) synthase, which catalyzes the reaction outlined in Scheme 1; EPSP synthase is of interest as the primary target for the broad-spectrum herbicide glyphosate (N-(phosphonomethyl)glycine (GLP)) which is the principal ingredient of Roundup®.

This enzyme has been extensively studied by kinetic and biophysical methods since the late 1980s. Direct observation of the enzyme-bound intermediate complex by solution-state NMR was first reported in 1989,(192,193) and later confirmed by another laboratory.(194) This is illustrated in Figure 17. Some site-directed mutants of the enzyme by steady-state kinetics, kinetic isotope effect analysis, fluorescence spectroscopy, and solution-state 31P-, 13C-, and 15N-NMR spectroscopy have since been characterized.(195–198) The enzyme has also been characterized qualitatively by solid-state REDOR NMR spectroscopy,(199) and a quantitative REDOR study has been completed.(200)

In time-resolved solid-state NMR, the enzyme and substrate are mixed together very rapidly and fired into a secondary cryogen such as liquid propane cooled to about 85 K.(201–206) This rapid freeze–quench generates a snow that can be packed in a solid-state NMR rotor for subsequent NMR analysis. In this manner enzymatic
The time-resolved solid-state NMR technique has been successfully applied to EPSP synthase and uridine diphosphate N-acetyl glucosamine enolpyruvyl transferase (UDP-NAG EPT). The work with EPSP synthase (Figure 18) showed that it was possible to use solid-state NMR to follow the build-up of the intermediate (with concomitant loss of substrate and build-up of product) under pre-steady-state kinetic conditions. These studies confirmed the intermediates reported by Anderson and Johnson, determined by chemical quench methods.

Time-resolved solid-state NMR has been coupled with REDOR for qualitative structural studies of complexes of EPSP synthase and UDP-NAG EPT, and REDOR used as an editing technique in combination with time-resolved solid-state NMR to detect the transient enzyme–intermediate of EPSP synthase. REDOR dephasing on a nucleus unique to the substrate or intermediate can be used to illuminate a sphere of a radius defined by the limit of the technique, and to light up selected residues within the vicinity if they are appropriately isotopically labeled (Figure 19). Following a report for a new mechanism for EPSP synthase, quantitative REDOR measurements on several species formed during the enzymatic reaction proved the proposed new mechanism to be incorrect. The X-ray structure of the unliganded form of EPSP synthase has been reported, but to date there has been no published report of the structure in the presence of substrates. It is known that substrates induce a conformational change, and it is thought that the protein shifts to a closed form. Therefore, several attempts have been made to characterize the structure of the closed conformation by NMR. In order to carry out intramolecular and intermolecular distance measurements by dipolar recoupling techniques, it is necessary to have a fixed site on the protein whose location has been established unambiguously, and make measurements either within the protein or to substrates whose location is also known. The weakness of some work in this field is ambiguity as to the location of one or other partner in the dipolar-coupled spin pair. This is a nontrivial problem, because techniques for site-specific isotopic labeling of proteins are generally insufficiently developed to be able to generate NMR quantities of sample. Uniform isotopic labeling is problematic because making sequence-specific assignments by solid-state NMR is not yet possible for proteins of 46 kDa. This laboratory is in the process of introducing a number of novel approaches to site-specific labeling and carrying out dipolar recoupling measurements to generate a limited set of
Deviations from idealized covalent geometry

The precision of the coordinates is defined as the average atomic RMS difference between the 35 individual simulated annealing structures of each complex and the mean coordinates \(\overline{x}\) of the restrained regularized mean coordinates for the two complexes obtained by restrained regularization of the mean SA coordinates. The number of terms for the various restraints is given in parentheses with the first number referring to the DBD2–DNA complex and the second to the DBD3–DNA complex.

\(\overline{x}\) is the mean of the coordinates for the two complexes obtained by averaging the coordinates of the individual SA structures best fitted to each other (with respect to residues 6–19 of the protein DBD2 and residues 32–41 of the protein DBD3, and base pairs 1–12 of the DNA). \(\overline{x}\) are the restrained regularized mean coordinates for the two complexes obtained by restrained regularization of the mean SA coordinates. The number of terms for the various restraints is given in parentheses with the first number referring to the DBD2–DNA complex and the second to the DBD3–DNA complex.

\(^b\) None of the structures exhibited distance violations greater than 0.5 Å, dihedral angle violations greater than 5°, \(3J_{	ext{iso}}\) coupling constant violations greater than 2 Hz, or \(J_{	ext{iso}}\) coupling constant violations greater than 0.5 Hz.

\(^c\) The number of NOEs involving \((r-6)^{-1/6}\) sum restraints to multiple DNA protons is 27 for the DBD2–DNA complex and 3 for the DBD3–DNA complex.

\(^d\) The hydrogen bond restraints within the DNA were used to maintain Watson–Crick base pairing.

\(^e\) The NC \(z\) atom of a lysine or guanidino nitrogen atoms of arginines were restrained within 7 Å of a DNA phosphate atom when NOEs from a residue (Lys7, Arg8, Lys14, Lys17, Lys19, Arg33 and Lys41) or when structure calculations and \(^{15}\)N relaxation measurements (Lys34 and Lys40) indicated that residue interacts with a DNA phosphate. \((r-6)^{-1/6}\) sum restraints were used and in each case a choice of two adjacent phosphate atoms was given.

\(^f\) In the final stages of the structure calculations two types of restraints were introduced to facilitate convergence. First, repulsive distance restraints were used to prevent energetically unfavorable proximity of hydrogen bond donors to other donors, and hydrogen bond acceptor groups to other acceptors: there were 11 such restraints for the DBD2–DNA complex and 10 for the DBD3–DNA complex. Second, a small number of repressive restraints were used to prevent structures being generated which predicted short interproton distances (<3 Å) for which no corresponding NOEs could be observed: there were nine such restraints for the DBD2–DNA complex and 18 for the DBD3–DNA complex.

\(^g\) The improper torsion restraints serve to maintain planarity and chirality.

\(^h\) \(E_{	ext{L-J}}\) is the calculated Lennard–Jones van der Waals energy and is not included in the target function for simulated annealing or restrained minimization.

\(^i\) The precision of the coordinates is defined as the average atomic RMS difference between the 35 individual simulated annealing structures of each complex and the mean coordinates \(\overline{x}\). The values refer to residues 6–19 and 32–41 of DBD2 and DBD3, respectively, and to base pairs 1–12 of the DNA.
accurate long-range distance restraints. These are being used in conjunction with short-range NOE-derived distance restraints from solution-state NMR data to solve the structure of the closed conformation of EPSP synthase. Figure 20 shows the HSQC spectrum of an N-terminal fragment of EPSP synthase, and Figure 21 shows the divide-and-conquer strategy taken to solve such a large protein structure.

5.3 Membranes

As membranes and membrane proteins cannot easily be crystallized, NMR spectroscopy is a particularly powerful method for probing their structure and function.\(^{219-221}\) This section considers the membrane protein gramicidin A, whose structure has been determined in the presence of lipid bilayers.

Gramicidin A is a small hydrophobic peptide composed of 15 alternating L- and D-amino acids (\(M_r \approx 1600\)).\(^{222}\) The peptide dimerizes and forms channels that conduct monovalent cations. There are substantial differences between two X-ray crystal structures of the peptide,\(^{223,224}\) and the bilayer structure that has been proposed on the basis of circular dichroism
Figure 19 Nitrogen-15-detected, $^{31}$P-dephased CP/MAS solid-state REDOR difference ($\Delta S$) NMR spectra of [U–$^{15}$N]EPSP synthase $^3$[P] plus a variety of inhibitors/substrates: (curve a) GLP at 295K; (b) 3-(Z)-fluoro-PEP at 273K; (c) [2-$^{13}$C]PEP under time-resolved conditions at 223K; (d) the full echo spectrum ($S_0$) of the sample in (a). Resonances due to a subset of lysine and arginine residues within a 6-Å radius of the substrates suggest that these residues are located in the enzyme-active site. A histidine residue putatively located in the enzyme-active site is clearly not detectable. Unfortunately, although the numbers of proximal lysine and arginine residues can be estimated, no site-specific assignments can be made from these data. (Adapted from ref. 192 with permission.)

measurements. Such a controversy is amenable to solution by NMR methods.

Cross et al. have conducted a set of experiments using orientation-dependent solid-state NMR studies to address the structure of gramicidin in membranes. $^{170,225–227}$ They examined by $^{15}$N- and $^{13}$C-NMR samples of gramicidin, specifically [${^{15}$N}] and [${^{13}$C}] labeled at particular residues, and oriented between glass plates in lipid bilayers. They succeeded in determining the structure by measurement of dipolar splittings and calculating $\phi$ and $\psi$ torsion angles. Figure 22 shows the spectra from gramicidin, $^{15}$N-labeled at Ala3 and Leu4. The measurements are of the Gly2–Ala3 and Ala3–Leu4 peptide bonds and the dipolar splittings ($\Delta \nu$) of the amide $^{15}$N resonances resulting from the directly bonded carbonyl carbons. The top spectra show the spectra of oriented gramicidin singly $^{15}$N-labeled at the amide nitrogens of Ala3 (left) and Leu4 (right), and the lower spectra show the dipolar splitting of the $^{15}$N by $^{13}$C when the peptide bonds are doubly labeled. The observed dipolar splittings are 670 Hz for the $^{13}$C-Gly2–$^{15}$N-Ala3 bond and 820 Hz for the $^{13}$C-Ala3–$^{15}$N-Leu4 bond. An accurate

Figure 20 The $^{15}$N-HSQC of the N-terminal domain of EPSP synthase. The spectrum displays reasonably good dispersion and resolution for a 23-kDa protein (the size of the N-terminal fragment). However, even when spread in three dimensions, as with an HNCO experiment, it is not sufficiently well-resolved for a complete assignment. Deuterium labeling is necessary to achieve adequate resolution.

Figure 21 The divide-and-conquer strategy for attempting to solve the solution-state NMR structure of EPSP synthase. The N- and C-terminal domains are expressed separately, and after reconstitution can be isotopically labeled separately, thereby halving the resonance overlap problem for this 46-kDa protein.
bond length is the only additional information needed to calculate the angle $\theta$. A 1.34-Å C–N bond length taken from the crystal structure of alanylalanine translates into a dipolar coupling constant $D$ of 1.26 kHz, so from Equation (45), these data define four possible orientations for each C–N bond because $D$ is larger than the observed splittings.

To limit these possibilities, independent restraints on the peptide plane orientations are obtained from the $^{15}$N–$^1$H dipolar couplings and the $^{15}$N chemical shift tensor. The $^{15}$N–$^1$H dipolar couplings are determined using separated local field experiments. These experiments are designed to separate the dipolar couplings from the chemical shifts. They can also be used to relate the chemical shift and dipolar coupling tensors and, as the latter is readily related to the molecular coordinate system, the orientation of the principal components of the shift anisotropy can be determined directly. In gramicidin, the separated local field experiments yield only two possible orientations for each N–H bond, because the $^{15}$N–$^1$H dipolar coupling constant is smaller than the observed splittings. As the orientation of the $^{15}$N chemical shift tensor relative to the molecular frame has been established independently by reference to model compounds, the observed $^{15}$N chemical shifts provide a way to discriminate between several of the orientations of the N–H and N–C bonds implied by the dipolar couplings. These data, together with additional geometric restraints, define two possible sets of torsion angles for the Ala3 position with errors in the $\phi$ and $\psi$ angles of $\pm 6^\circ$ and $\pm 5^\circ$ respectively (Figure 23).

The two structures defined by the Ala3 torsion angles are right-handed $\beta$-type helices. The difference between the two structures is the orientation of the carbonyl group with respect to the channel axis, which in the upper structure (a) points towards the channel ($\psi = 153^\circ$) and in the lower structure (b) points away from it ($\psi = 122^\circ$). Structure (a) is the favored model because it is biologically sensible, because the selectivity of cations over anions by gramicidin might arise because of the partial negative charges of the backbone carbonyls, which could solvate the cations after they have been stripped of water as they enter the channel.

An alternative approach has been adopted by Schaefer et al., who used 2D REDOR on Val1-[1-13C]Gly2-[15N]Ala3-gramicidin A in multilamellar dispersions.

---

**Figure 22** $^{15}$N spectra of gramicidin A in DMPC (dimyristoylphosphatidylcholine) bilayers. The top spectra are of gramicidin singly labeled with $^{15}$N at the amides of (a) Ala3 and (b) Leu4, and the bottom spectra illustrate the dipolar splitting observed when the peptide bonds are doubly labeled with $^{13}$C. (Reprinted from ref. 170 with permission.)

**Figure 23** Two possible structures for the peptide planes at Ala3 in gramicidin A. Both correspond to right-handed $\beta$-type helices but differ in the orientation of the Ala3 carbonyl group, which points toward the gramicidin channel axis (left) or away from it (right). (Reprinted from ref. 170 with permission.)
of DMPC to measure dipolar couplings and infer from these four possible angles between the Gly2-Ala3 $^{15}$C–$^{15}$N peptide bond. This information supported a right-handed single-stranded helical dimer as a structural model for gramicidin in multilamellar dispersions.

We have given a detailed description of how torsion angle restraints were derived for one set of dipolar splittings. Cross et al.\textsuperscript{234--237} have carried out a systematic determination of the structure of the backbone and side-chains for gramicidin in a lipid environment using 141 orientational restraints derived from measurements of $^{15}$N chemical shift anisotropy, $^{15}$N–$^1$H and $^{15}$N–$^{13}$C dipolar splitting, and $^2$H quadrupole splitting. The final structure, shown in Figure 24, was calculated using an algorithm similar to simulated annealing on a set of 40 random structures, and had RMSDs of $\pm 5^\circ$, which reflects the very high precision of the solid-state NMR measurements.

**ACKNOWLEDGMENTS**

I should like to thank members of my research group past and present (Paul Barlow, Richard Appleyard, Wendy Shuttleworth, Cecilia Ramilo, Yan Li, Jaroslav Zajicek, Tatyana Igumenova, Dan Mitchell, David Jakeman, Greg Helms, and Melissa Pohl) for their help with much of the work described here. I should also like to acknowledge Angela Gronenborn, Marius Clore, Jeff Huth, Carole Bewley, Dan Garrett, Frank Delaglio (The National Institutes of Health) and Mark Nissen and Ray Reeves (WSU) for their kind help. This work was supported by NIH grant GM43215. The WSU NMR Center equipment was supported by NIH grants RR0631401 and RR12948, and NSF grants CHE-9115282 and DBI-9604689.

Raman spectroscopy (RS) is a vibrational spectroscopy technique, based on the phenomenon of inelastic light scattering from matter (the Raman effect). It is an irreplaceable tool for the study of biological events at the molecular level and for identification of biomolecules. There are several reasons for this. First of all, RS measures the vibrations of atoms. This implies that the positions of the bands, widths and intensities are sensitive to the molecular structure, and minor perturbations induced by intramolecular or intermolecular interactions can easily be followed. Vibrations of some molecular groups are very characteristic (characteristic vibrations) and therefore can be used for the identification of certain groups or even whole molecules. In addition, work using isotope labeling, model compounds, site-directed mutagenesis and normal coordinate analysis has led to the identification of so-called marker bands, which serve as a bridge in establishing spectrum–structure correlations. Second, water causes weak Raman scattering, and consequently biomolecules can be studied in their natural environment without solvent interference. The third reason for the growing interest in RS is related to the considerable intensity enhancement (up to 10^6) observable in resonance Raman spectroscopy (RRS) and surface-enhanced Raman spectroscopy (SERS). Important structural units, such as chromophoric active centers, aromatic amino acid residues, bases of nucleic acids, and peptide bonds, can be studied selectively by exploring the resonance Raman (RR) phenomenon and tuning the excitation wavelength (λ_ex) into the electronic absorption band of certain structural elements. Such an approach allows the major problem in vibrational spectroscopy of biomolecules to be overcome – namely interpretation difficulties due to overlapping of numerous bands. Because the Raman effect is inherently weak, the future for analytical applications is closely connected with both RRS and SERS. The combination of these two methods might be especially productive. Fourthly, because the Raman effect is instantaneous (timescale in the order of 10^-14 s), and due to the recent advances in laser technology, the time-resolved action of biomolecules down to picosecond resolution can be followed, retaining the value of structural information. The ability to focus a laser beam down to the dimensions of λ_ex is the fifth advantage of RS. Combined with RRS or SERS, this approach allows the composition of a single living cell to be analyzed.

To explore fully the advantages of RS, the limitations of the technique must also be considered. First of all, the probability of Raman scattering is very low, so the effect is weak and high concentrations of biomolecules are required. Secondly, in RR experiments excitation within the electronic absorption band often causes photodegradation of the active center in the biomolecule. To avoid such problems, low laser powers, moving samples and independent inspection of the sample integrity are often employed. The same problems are also present in the SERS field. Overheating by the laser beam could be an obstacle in Fourier transform Raman (FTR) studies. Finally, many active centers in biomolecules, or impurities in the sample, exhibit intense fluorescence (Fl), obscuring the Raman spectra.
1 INTRODUCTION

The Raman effect arises from the interaction of incident photons with electrons of the matter under investigation. During this interaction the photons can lose (Stokes’ process) or gain (anti-Stokes’ process) energy equal to the vibrational energy of the atoms. Consequently the vibrational energy of the atoms increases or decreases. Such communication is possible for the motions of atoms, which modulate the polarizability of the molecule. Intense Raman bands will be observed from nonpolar groups, particularly aromatic rings, the vibrations of which produce considerable modulation of polarizability. The resulting Raman spectrum, presented in wavenumbers (cm\(^{-1}\)) as the difference between the excited and emitted photon energy, is the vibrational spectrum of the molecule. The effect is very weak, because the energy exchange probability is low. Only one in \(\sim 10^6\) of the incident laser photons is converted to a Raman photon.\(^1\)

The timescale of the scattering process is in the order of \(10^{-14}\) s, so the effect is extremely fast.\(^2\) In the Raman process it is important that the vibrations of the atoms are not probed directly by the incident photons, but through the interaction with the electron cloud. Thus the state of the electrons is also significant and when the energy of incident photons approaches the electronic transition the intensity in Raman spectra is enhanced up to \(10^6\) times (RR effect).\(^3\) As we will see this unique possibility determines the face of modern biomolecular RS.\(^1–9\)

RS has the following main advantages which make it attractive for biologists:\(^1–8\)

1. structural sensitivity
2. intrinsic weak scattering from water
3. RR and surface-enhanced Raman (SER) phenomenon
4. possibility to design various kinds of time-resolved experiments with picosecond resolution
5. possibility to focus laser beam down to the dimensions of \(\lambda_{\text{ex}}\).

Vibrations of atoms depend on the mass and force field. Even minor perturbations in the force field induced by intermolecular or intramolecular interactions are reflected in the spectra, permitting the analysis of structural conformations, bonding strength, and phase transitions. In addition, isotopic labeling perturbs the mass of the system and the location of particular vibrational modes in the spectra can be identified. The motions of atoms in some groups are typical of that particular group, and are hardly affected by the rest of molecule or the environment (characteristic vibrations).\(^1\) Such bands are very useful for instantaneous identification of certain atomic groups in a biomolecule from its spectrum. Tremendous efforts in establishing correlations between spectra and structure, using isotope labeling, model compounds, site-directed mutagenesis and normal coordinate analysis, have led to the identification of certain marker bands, whose position or intensity is directly dependent on the structure and state of the particular group. For example, marker bands provide information on the redox and spin state of the heme group in heme proteins,\(^7\) the secondary structure of polypeptides,\(^6,7\) the state and bonding of amino acid residues,\(^6\) the structure and stacking of nucleic acid bases,\(^6\) and melting phenomena in phospholipid bilayers.\(^6,7\) Structural transformations of biomolecules can be followed by RS in water, i.e. in their natural environment, without serious interference from the solvent. Water causes weak Raman scattering, since vibrations of the highly polar O–H bonds produce only minor polarizability changes. Although Raman spectra mainly contain structural information, the application of conventional RS to real systems is hindered by the complexity of biomolecules. Indeed, proteins routinely contain thousands of atoms. Because the number of normal vibrations for an \(N\)-atom molecule is \(3N – 6\) (or \(3N – 5\) for linear molecules), it is clear that in general spectra contain too much information and consist of many overlapping bands, which cause serious interpretation problems. Fortunately, resonance enhancement (when \(\lambda_{\text{ex}}\) lies within the electronic absorption band) and surface enhancement (at roughened Ag, Au and Cu surfaces) effects have been discovered.\(^9\) In RR studies only the vibrations of chromophoric groups are enhanced in intensity (up to \(10^6\) times), considerably simplifying the spectra. Because different structural units exhibit absorption at different wavelengths, tuning the \(\lambda_{\text{ex}}\) makes it possible to selectively probe each unit. Combination of surface and resonance enhancements in surface-enhanced resonance Raman spectroscopy (SERRS) appears extremely promising for analytical purposes, as in some cases concentrations of analytes can be reduced down to \(\sim 10^{-10}\) M. and also because of considerable FI damping. Reports on the detection of single dye molecules have appeared.\(^10,11\) Unlike FI studies, it is important that the vibrational spectrum from a single molecule contains structural information and characteristic vibrations. The development of reliable and more reproducible sample preparation protocols will expand the analytical applications. The function of biomolecules cannot be understood without knowledge of the evolution of structural transformations over time, as well as the formation of various transient states and species. Time-resolved RS\(^9\) is particularly attractive for fundamental biophysical and biochemical studies because of the combination of molecular level information intrinsic to vibrational spectroscopy with time resolution from milliseconds to picoseconds. Events faster than 1 ps can
also be followed by time-resolved RS, although due to the uncertainty principle the spectral resolution will be reduced. Achievements in this field of RS are directly connected to recent developments in pulsed laser technology. Another field of biospectroscopical research has emerged from the combination of vibrational information with spatial resolution, in the form of micro-Raman spectroscopy (MRS). The laser beam can be focused to the dimensions of light wavelength. Consequently, spatial resolution depends on the wavelength of $\lambda_{\text{ex}}$. For biologists this opens the possibility of examining compositions of the components of living cells. The combination of RR and/or SER effects with MRS appears to be extremely promising for clinical research.

The advantages of RS for biomolecular studies cannot be fully explored without considering the following main limitations: (1) Raman scattering is a weak phenomenon; (2) the sample may undergo photodegradation by the laser beam; (3) the sample may be heated by the laser beam; (4) Fl.

Because Raman scattering is weak, high concentrations of the biomolecules are required. Typical concentrations of nucleotide or peptide groups in nonresonance RS should be in the order of $0.03–0.1 \text{ M}$. In RRS and SERS these concentrations can typically be reduced down to $10^{-8}$–$10^{-5} \text{ M}$. However, the influence of the laser beam on the sample must be very seriously considered in RRS and SERS experiments. Absorption of photons by the molecular group under investigation (in RRS) or by the surface (in SERS) often leads to photodegradation or denaturation of the biomolecule due to the increased temperature. Overheating problems also should be considered in FTR experiments as water absorbs laser beams at 1064 nm. Fl is intrinsic for many chromophoric active centers in biomolecules, and can obscure the Raman spectrum completely, due to its higher efficiency (up to $10^8$ times). Additional source of Fl is traces of impurities in the sample. This problem has seriously restricted routine applications of RS to biomolecules. Tuning $\lambda_{\text{ex}}$ in the near-infrared (NIR) region as well as application of FTR techniques may overcome this limitation.

In summary, RS in its various forms provides valuable information on the structure of the molecule and its interactions. In particular, certain structural units and chromophoric centers can be probed selectively by exploring the RR approach. In addition, because of the fast response time rapid structural transformations can be followed. Such information is the basis for a long-standing goal of biochemists and biophysicists – to understand the mechanisms of biological phenomena at a molecular level. The structural sensitivity is also extremely attractive for analytical purposes, as it can be used to identify certain biologically active functional groups or biomolecules in different environments and mixtures. A major breakthrough in analytical applications is expected from the combination of RRS and SERS. The possibility of detecting biomolecules at trace level is becoming a reality in universities and research institutes. The development of more reproducible and reliable surface preparation protocols will shift this field to more applied laboratories and clinical units.

The goal of this article is to provide orientation on the advantages and limitations of RS, and thus to stimulate the application of this technique to the analysis of biomolecules. We hope to provide an idea of the structural information extractable by different kinds of RS.

Characteristic vibrations and marker bands are the basis of many RS works, and are provided in many sections. It is believed that those bands serve first of all as illustrations in spectra–structure correlations, but can also be used independently in some studies using RS. Selected examples will demonstrate what kind of problems in the analysis of biomolecules can be addressed by RS.

2 HISTORY

The Raman effect was discovered experimentally in 1928 by Raman and Krishnan, and independently by Landsberg and Mandelstam. The importance of the discovery was immediately appreciated by the scientific community, and in 1930 Raman received the Nobel Prize in physics. In 1952, the resonance enhancement effect was observed experimentally by Shorygin. These results were presented in 1953, at a meeting in Gmunden, Austria. In the early, mercury lamp history of RS the biological applications were secondary. Not until 1958 did Garfinkel and Edsall record the first Raman spectrum of a protein, lysozyme. They used a high-pressure mercury lamp for the scattering excitation and photographic plates for the detection. The important step towards a deeper understanding of the structure of proteins came with the determination of the normal vibrational modes of the peptide group in N-methylacetamide by Miyazawa et al. in 1958. Further attempts in this direction led to the elucidation of some useful correlations between the amide vibrational spectra and the secondary structure.

The discovery of lasers stimulated tremendous growth of Raman applications and in 1968 a report on the first laser-excited Raman spectra of proteins appeared. Two years later Long and Loehr introduced the resonance enhancement effect for the analysis of the
active site of the iron–sulfur protein, rubredoxin. Further application of RRS to biomolecules (heme proteins) led to the discovery of the inverse-scattering polarization phenomenon by Spiro and Strekas in 1972. This discovery stimulated the development of RR theory and had an impact on general RS. The possible use of RS in model membrane studies was first demonstrated in 1971 by Lipperd and Peticolas. At this time several new and powerful Raman techniques emerged. Barron and Buckingham predicted Raman optical activity (ROA) in 1971. Two years later the effect was observed experimentally by Barron et al. An interesting and unpredicted discovery, the SER effect, was observed in an electrochemical cell in 1974. In 1980, after understanding the main features of the effect, first surface-enhanced resonance Raman (SERR) spectra of the adsorbed proteins cytochrome c (cyt c) and myoglobin (Mb) were reported at a silver electrode, from solutions containing $10^{-6}$ M concentrations of proteins. Further development of this technique led to single-molecule detection sensitivity.

It is clear from this brief historical overview that biomolecular RS is open for fascinating new discoveries and powerful applications. For example, in 1998 the first ROA spectra from DNA and RNA were reported by Bell et al. opening the new field of direct study of chiral elements in biomolecules.

3 COMPARISON OF RAMAN METHODS

The characteristic mark of modern RS is the variety of techniques used to explore the Raman effect. Table 1 summarizes the main advantages and limitations of methods useful for biomolecular applications. To overcome the selectivity and sensitivity limitations characteristic of classical nonresonant RS, the RR and ultraviolet resonance Raman (UV/RR) approaches are extremely powerful. Most importantly, by tuning the different parts of biomolecules can be selectively probed. This approach will be demonstrated in section 4.

SERRS allows adsorbed species to be detected at concentrations in solution of the order of $10^{-10}$ M. Today this is the most sensitive vibrational technique. However, the price for such sensitivity is the adsorption requirement, which frequently causes denaturation or structural transformations. To preserve the function and structure of biomolecules at surfaces lowering of the temperature or modification of the electrode surface by preadsorbed organic molecules or ions has been suggested. In addition, the possibility of photodegradation should be considered seriously in SERRS, SERS, and RR experiments. Various ways of moving or rotating the sample can effectively decrease the destructive influence of the laser beam, and will be considered in more detail. Finally, FTR instruments are very attractive for routine analysis of rather concentrated samples, due to the absence of the FI problem and their simplicity to use.

4 INTERPRETATION OF RAMAN SPECTRA

Assignment of the bands is the bridge between recorded spectra and normal vibrations of molecules. It is the first step necessary for the application of RS in analysis of biomolecules. The major problem is the complexity of the spectra. In this section we will demonstrate how the combination of several Raman techniques, isotopic substitution, site-directed mutagenesis and depolarization ratio ($\rho$) measurements is able to considerably simplify the task. Normal-coordinate analysis, although a very powerful tool for the assignment of bands, is out of scope of this article and will not be discussed here.

4.1 Combination of Several Raman Techniques

One of the most serious limitations preventing the application of classical vibrational spectroscopy to biomolecules is that the spectra are too complex and overlapped, due to the large number of atoms in the molecule. An elegant solution to this limitation is the application of several Raman techniques to the same sample in combination, providing the possibility of seeing the molecule at different angles. The unique power of combined visible resonance Raman spectroscopy (VIS/RRS) and ultraviolet resonance Raman spectroscopy (UV/RRS) is demonstrated in Figure 1. Electronic absorption transitions from different protein structural units can be observed in the absorption spectrum:

1. heme charge transfer (CT) band at 600 nm that contains transitions involving the metal ion and the axial ligands;
2. strong $\pi \rightarrow \pi^*$ Soret transition in heme group at 400 nm;
3. absorption of aromatic amino acid residues (Trp and Tyr) in the 260–220 nm range;
4. peptide backbone amide $\pi \rightarrow \pi^*$ transition below 220 nm.

As can be seen from Figure 1, by tuning $\lambda_{ex}$ from 600 nm to 210 nm it is possible to selectively probe different structural units in the protein:

1. iron–fluoride (axial ligand) stretches and heme in-plane ring vibrations;

Figure 1 Selective probe of different structural units of sperm whale Mb by RRS: (a) absorption spectrum; (b) ultraviolet (UV) excitation at ~225 nm enhances tyrosine (Tyr) and tryptophan (Trp) bands (structures shown); (c) excitation further in the UV region enhances amide vibrations whose intensities and frequencies depend on the protein secondary structure (structure of amide group shown). Excitation within the heme absorption bands in the visible spectral region (400–600 nm) enhances vibrations only of (d) the heme ring (structure shown) and (e) vibrations between the heme iron and its axial ligands. No protein vibrational modes are observed. [Reproduced by permission of American Chemical Society from S.A. Asher, Anal. Chem., 65(4), 201A–210A (1993).]
4.2 Isotopic Substitution

Vibrational frequencies are determined by the force field and masses of the atoms. Isotopic substitution selectively affects the mass of the vibrating atoms at a particular place in the molecule, but in general does not influence the bonding properties between atoms. Consequently, isotopic exchange of atoms is reflected in the frequencies as isotopic shift (Δ). Isotopic substitution plays a key role in solving the following problems:

(1) assignment of the vibration of a particular molecular group in the spectrum;
(2) coupling between vibrations;
(3) identification of the ligand and its binding mode (for example, it is possible to determine the number of identically bonded atoms using isotopically labeled ligand atoms).

As interpretation of the vibrational spectrum is one of the major problems in biospectroscopy, direct assignment of the vibrations of particular molecular groups in the spectrum through isotopic substitution is an indispensable tool in RS. The largest Δ is observed when H is replaced by D. The simplest way to produce such an exchange in biomolecules is by using D₂O as a solvent. The hydrogen atoms attached to N, O, and S atoms are mobile and will spontaneously exchange with deuterium provided these groups have sufficient accessibility to the solvent. The frequency ratio can be evaluated by using Equation (1) for two atom molecules:

\[ \nu(m_1m_2) = \frac{1}{2\pi} \frac{k}{m_1m_2} = \frac{1}{2\pi} \frac{k}{\mu} \]  

Equation (1)

where \( m_1 \) and \( m_2 \) are the masses of the atoms, \( k \) is the force constant, and \( \mu \) is the reduced mass. The calculation for the particular \( \nu(\text{NH})/\nu(\text{ND}) \) case is shown in Equation (2).

\[ \frac{\nu(\text{NH})}{\nu(\text{ND})} = \frac{\sqrt{(14+1)/(14 \times 1)}}{\sqrt{(14+2)/(14 \times 2)}} \approx 1.37 \]  
Equation (2)

This means that the stretching vibration of the N-H bond, for example in the amine group of the lysine amino acid residue, will shift from ~3300 cm⁻¹ to ~2360 cm⁻¹. From Table 3 in section 6.1, we can see that such a shift is indeed observed and helps to assign vibration of this group in the spectra. Coupling between vibrations arises when atoms of similar masses are connected in the molecular group by similar strength bonds. For example, separate stretching vibrations of N-H, C-C, or C-O bonds cannot be found in the N-H-CH₂-CH₂-O- group. Isotopic exchange of ¹⁴N/¹⁵N in this molecular group would lead to shifts in positions of several bands, thus indicating those vibrational modes and how much they are coupled with the motion of the N atom. The extent of the coupling can be recognized roughly from the Δ value (the stronger the coupling, the larger the Δ value). An interesting example is coupling between ring vibrational modes with N-H deformation in the imidazole ring of histidine (His). As shown in section 6.1, perturbations in coupling between vibrations induced by the replacement of the N-H group by the N-D group in acidic D₂O solutions result in completely different Raman spectra, featuring a very strong peak at 1408 cm⁻¹. This band from the protonated imidazole ring in D₂O solutions serves as the best His residue marker band for analytical purposes. Blue copper proteins are the other important examples of vibrational coupling. As shown in section 6.2, the isotopic ³²S/³⁴S and ¹⁴N/¹⁵N substitutions in the molecular group Cu-S-β-Cα-N induce clear shifts in all the observed low-frequency RR modes, showing that all the bands are generated by the \( \nu(\text{Cu-S}) \) stretching vibration coupled with the deformations of the Cu-S-β-Cα-N moiety. In studying coupling phenomena, isotopic substitution experiments combined with normal coordinate analysis⁽¹,²⁾ are the most powerful tools.

Figure 2 demonstrates how isotopic substitution helps to understand protein-ligand bonding in cytochrome bd.
4.3 Mutation

Replacement of the entire amino acid residue in a protein through mutation combined with RS opens a way to study

(1) properties of individual amino acid residues
(2) effects of mutation on protein structure
(3) architecture and spectroscopy of the active centers in proteins.

The ionization state of carboxyl groups has been monitored by comparing nonresonant Raman difference spectra of the wild-type protein and a mutant in which the carboxyl group was replaced by serine. New insights into the spectroscopy of the active site of the blue copper protein, azurin (Az) have been revealed by the mutation of the His ligand to glycine (Gly). In the active site of Az, the Cu ion is strongly coordinated by three ligands: one S atom from the cysteine (Cys) residue, and two N atoms from imidazole rings of His residues. The problem lies in deciding which of the bands in multiple RR spectra correspond to the Cu~N vibration. It was shown that mutant Az is able to bind exogenous ligands. This approach opens the way to constructing an active site in which the Cu ion coordinates 15N-labeled imidazole, simply by introducing isotopically labeled imidazole in the solution containing mutated protein. No isotope dependence was observed in the RR spectra of Az mutant reconstituted with 15N-imidazole, indicating that His ligands do not contribute significantly to the spectrum of Az.

4.4 Depolarization Ratio Measurements

The depolarization ratio ($\rho$) is defined as shown in Equation (3)

$$\rho = \frac{I_\perp}{I_\parallel}$$

where $I_\perp$ and $I_\parallel$ refer to the intensities of scattered radiation polarized perpendicular and parallel to the incident light, respectively. Such measurements can be performed very easily for biomolecules in solution by placing the analyzer in the path of scattered Raman light between the sample and slit. Two spectra must be collected at perpendicular and parallel rotations of the analyzer. Thus $\rho$ can be estimated for each band in the spectra. Important information about the symmetry of vibrational modes, which is critical in performing assignments of the bands, can be extracted from the $\rho$ value:

- $0 < \rho < 3/4$ for totally symmetric (polarized) vibrations
- $\rho = 3/4$ for nontotally symmetric (depolarized) vibrations
3/4 < \rho < \infty \) for anomalous (inverse) polarized vibrations (can only be observed in RR spectra).

The phenomenon of anomalous polarization was discovered in studies of heme proteins, hemoglobin and cyt c.\(^{(22)}\) Polarization measurements were critical in making assignments in the RR spectra of complex heme proteins. Totally symmetric (A\(_{1g}\)), nontotally symmetric (B\(_{1g}\) and B\(_{2g}\)) and anomalously polarized (A\(_{2g}\)) bands were distinguished.

5 EXPERIMENTAL

The classical Raman spectrometer consists of the following main components:

1. excitation source (laser);
2. sample illumination;
3. sample holder;
4. scattered radiation collection system;
5. monochromator or spectrograph;
6. detection system [photomultiplier or charge-coupled device (CCD) camera].

The focus in this section will be on sampling schemes, avoiding laser effects on the integrity of the biomolecules, and calibration of the spectrometer.

5.1 Sample Handling

Laser-induced photodegradation of the sample is a major concern in RRS, UV/RRS, SERS, and SERRS experiments (Table 1). The principal solution used to avoid this effect is based on moving the laser spot relative to the sample. Such a procedure decreases the illumination time per sample volume or area. Rotating liquid sample cells,\(^{(40)}\) liquid samples flowing through capillaries, rotating electrodes,\(^{(41)}\) moving electrochemical cells,\(^{(42)}\) and scanning beam techniques\(^{(43)}\) have been developed. Some of them are shown in Figure 3.

5.2 Frequency and Intensity Calibration

Various methods\(^{(44–46)}\) used for frequency calibration are compared in Table 2. The best accuracy can be achieved using neon emission lines. This method works very well for both one-channel detection systems (using photomultipliers) and multichannel detectors.\(^{(44)}\) The small red commercial pilot lamp is easily available. It is convenient to record Ne lines and Raman spectra of the sample simultaneously. After the calibration Ne lines can be subtracted using the reference spectrum recorded with a blocked laser beam. An extensive list of Ne emission lines is available\(^{(44)}\) in the wavelength range from 313 nm to 890 nm. As the Ne line method is an absolute wavenumber method, the exact \(\lambda_{\text{ex}}\) is required.
for recalculating the positions of the lines to the Raman shifts. If the precise $\lambda_{ex}$ is not known (for instance when working with dye lasers) it should be also calibrated against the Ne lines. The exact $\lambda_{ex}$ value is not required for Raman shift methods, because of the well-known peak positions of standard samples. A spectrum from indene, which is recommended by the International Union of Pure and Applied Chemistry (IUPAC) for frequency calibration, is shown in Figure 4. Indene should be purified before use by vacuum distillation.\(^{(2)}\)

Intensity calibration is a complicated issue in RS. Two aspects of the problem are considered in this section: estimation of the analyte concentration based on the intensity of the particular Raman band, and calibration of spectrometer sensitivity with respect to the wavelength (correction of relative intensities in the spectra). The intensity of the Raman scattering of a particular vibrational mode from the analyte molecule ($I_a$) depends on many factors,\(^{(2,45)}\) as shown in Equation (4):

$$I_a = I_0v^4K(v)A(v)\beta_a C_a$$

where $I_0$ is the intensity of the incident laser radiation, $v$ is the Raman frequency, $K(v)$ is the overall spectrometer response, $A(v)$ is the self-absorption of the medium (important for RR studies), $\beta_a$ is the molar Raman scattering parameter of the analyte molecules, and $C_a$ is the concentration of the analyte molecules. Because the parameters $K(v)$, $A(v)$, and $\beta_a$ are difficult to evaluate, relative rather than absolute intensities are employed in RS for $C_a$ determination. For this purpose many internal intensity standards may be used, such as the tetrahedral anions ClO$_4^-$ (935 cm$^{-1}$ band) and SO$_4^{2-}$ (981 cm$^{-1}$ band), or water bands ($\delta$(HOH) = 1640 cm$^{-1}$, $\nu$(OH) = 3400 cm$^{-1}$, and $\delta$(DOD) = 1204 cm$^{-1}$, and $\nu$(OD) = 2500 cm$^{-1}$). If parameters referring to internal standard molecules are denoted by $K(v')$, $A(v')$, $\beta_s$, and $C_s$, the relative intensity $I_a$(rel) = $I_a/I_s$ can be expressed as shown in Equation (5):

$$I_a$(rel) = $\frac{v^4K(v)A(v)\beta_a C_a}{(v')^4K(v')A(v')\beta_s C_s}$ = constant $\times C_a$$

The value of the constant may be determined easily by introducing a known amount of the analyte $C_a$(known). The calibration curves of Raman intensity versus concentration are linear.$^{(1)}$

Several methods have been proposed for the correction of spectrometer response with wavelength:

1. tungsten lamps
2. standard lamps from the National Institute of Standards and Technology (NIST);
3. pure rotational spectrum from D₂;
4. Fl spectrum from quinine.

The discreteness of the lines and narrow frequency range limit the application of the rotational Raman spectrum from D₂. The Fl method suffers from a rather narrow spectral range (400–600 nm) and the requirement to use a UV laser for the excitation of the radiation. The combination of a tungsten lamp and fiber optics was demonstrated to be a promising choice as the white light source for intensity calibrations (Figure 5). For the Raman intensity correction to the instrument response, the measured Raman spectrum should be divided by the white spectrum recorded from the tungsten lamp at the same experimental conditions.

6 APPLICATIONS TO BIOMOLECULES

This section will describe the applications of various kinds of RS to biological systems. Starting from the spectroscopic characterization of simple structural elements using marker bands, we will show how this knowledge can be applied to the molecular-level characterization of more diverse biological systems. The emphasis will be on the spectrum–structure correlations provided in the numerous tables.

Applications of RS to biomolecular studies are rapidly increasing. A number of excellent reviews have been published concerning studies of peptides, active centers of proteins, nucleic acids, membranes, dynamics of biomolecules, and microscopic applications.

6.1 Amino Acids and Peptides

Amino acids are the fundamental building blocks of proteins and therefore attract much attention from vibrational spectroscopists. The Raman technique was first applied to amino acids by Garfinkel and Edsall in 1958. From then on these systems have been extensively studied by nonresonance Raman, UV/RR, ROA, and SERS. The information obtained in such studies can be divided into three categories: identification, structural and conformational analysis, and interactions.

Precise identification of amino acid residues in proteins is a difficult task even for such a structure-sensitive technique as RS. This is because many functional groups present in proteins contribute to the spectra, and as a result the observed bands are broad and overlap. To overcome these difficulties a combination of several approaches is very useful. We will concentrate on three of them:

1. isotopic solution H₂O/D₂O exchange
2. variation of pH
3. application of the UV/RR technique.

The usefulness of such an approach can be seen from Table 3, where characteristic vibrations of the main functional groups of amino acids in different environments are summarized. The frequencies of the vibrations of N–H, O–H or S–H bonds containing exchangeable hydrogen atoms are lowered by a factor of approximately √2 going from H₂O to D₂O solutions. Such a big shift in principle allows identification of the amine (–NH₂), ammonium (–NH₃⁺) and sulphhydryl (–SH) groups (Table 3). For example, the sulphhydryl group can be immediately identified by the observation of the strong band in the 2560–2580 cm⁻¹ region in H₂O solutions, which shifts to 1850–1880 cm⁻¹ in D₂O. However, νₓ(NH₂) falls in the region of strong water scattering, and subtraction of a pure water spectrum is recommended. It should be noted also that full width at half-maximum (fwhm) for the N–H vibration in an –NH₂ group is considerably lower than vibrations of water. More serious problems are related to identification of the ammonium group. A high rate of exchange of protons and extended H-bonding interactions result in very high fwhm for these bands in addition to their

low intensity. In this situation the combined analysis of δ(NH$_3^+$)/δ(ND$_3^+$) vibrations (Table 3) might be helpful. It is not only direct vibrations of the bond involving hydrogen atoms that can be probed by the H$_2$O/D$_2$O exchange approach. For example, some bands from the indole ring of Trp residue and the imidazole ring from His residue clearly shift on deuteration (Table 3).

The effect is associated with the coupling of certain ring vibrations with deforming N–H motion. In the case of the Trp residue two strong features at 759 and 1012 cm$^{-1}$ can serve as the marker bands, and a slight shift of the first band to 754 cm$^{-1}$ in D$_2$O solutions can serve as a reliable confirmation of the assignment, but the analysis of His residues strongly requires isotopic addition experiments. Three main phenomena control the shape and structure of the vibrational spectrum of the imidazole ring in His, depending on environmental conditions:

(1) extensive coupling of ring vibrational modes with N–H deformation;

(2) increases in local symmetry from C$_s$ to C$_{2v}$ upon protonation of both N atoms in the imidazole ring (as a result the spectrum is considerably simplified);

(3) tautomerism of the neutral imidazole ring (Table 3).

The protonated, positively charged imidazolium ring can be undoubtedly identified by the strong and narrow band at 1408 cm$^{-1}$ which appears in D$_2$O solutions (Table 3). This band clearly dominates in the spectrum and serves as the best spectral signature for His residues. The symmetric stretching vibration $\nu_s$(COO) from carboxylate groups and the deformational motion $\delta$(CH$_2$) from methylene groups are possible interferences, although those bands do not change position in H$_2$O and D$_2$O solutions. Monitoring of the imidazole ring pK$_a$ is the second valuable application of the 1408 cm$^{-1}$ feature. On the other band, tautomerism should be investigated in H$_2$O and D$_2$O solutions. As can be seen from Figure 6, the amide I vibration is concentrated on the motion of the C=O bond.

$\epsilon$, Extinction coefficient.
group, while the other two modes have higher contributions from the in-plane bending of N–H, and therefore can be easily detected by their considerable frequency reduction in D$_2$O solutions. The amide II mode, usually very weak in nonresonant RS, appears as an intense band in UV/RRS, especially in D$_2$O solutions. The high contribution from the stretching C–N vibration results in the considerable resonance enhancement of this special vibration. Particular enhancement of the amide II mode comes from the transformation of this vibration to the $\nu$(CN) mode upon H→D exchange. The H-bonding between the hydrogen of the NH group and the oxygen of the CO group (Figure 6) is an essential component in determining the secondary structure of proteins. The H-bonding strength and rotation reflect on the amide frequencies. Thus different protein structures can be distinguished based on these frequencies, as shown in Figure 7. The frequency ranges presented demonstrate the basic trends in spectrum–structure correlations, although in each particular case such correlations should be considered with some caution. A selective probe of amide vibrations is possible through the UV/RR approach with $\lambda_{ex} < 220$ nm. The electronic absorption spectrum of the peptide group is characterized by three transitions: weak $n \rightarrow \pi^*$ at 220 nm; strong $\pi \rightarrow \pi^*$ at 190 nm; and $n \rightarrow \sigma^*$ at 165 nm. Excitation within the $\pi \rightarrow \pi^*$ transition enhances vibrational modes significantly coupled to $\nu$(C–N), i.e. amide II and III vibrations (Figure 6). Excitation within the $n \rightarrow \sigma^*$ absorption selectively enhances the amide I mode. A selective probe of amide bands in Mb with $\lambda_{ex} < 220$ nm is shown clearly in Figure 1.

6.2 Active Centers in Proteins

Active centers in proteins are mainly responsible for the particular biological function of the biomolecule.

![Figure 6](image_url) **Figure 6** Calculated vibrational amide modes of N-methylacetamide. Vibrational frequencies in H$_2$O (D$_2$O) and potential energy distributions (all contributions $\geq 0.1$ are included) are also shown. $\nu$, Stretching; $\delta$, deformation. [Reproduced by permission of Academic Press from S. Krimm, J. Bandekar, *Adv. Protein. Chem.*, 38, 181–364 (1986).]

![Figure 7](image_url) **Figure 7** Correlation between amide I and III wavenumbers and protein conformations. There are always exceptions in band wavenumbers, but the ranges shown in the figure usually cover the majority of bands for a given conformation. [Reproduced by permission of John Wiley & Sons from A.T. Tu, in *Spectroscopy of Biological Molecules*, eds. R.J. Clark, R.E. Hester, John Wiley & Sons, Chichester, 47–112, 1986.]

In metalloproteins, metal ions coordinated by protein amino acid residues or certain molecular groups serve as a catalytic center of enzyme action or are involved in the electron transfer process. In many cases such active centers are chromophores and thus can be studied selectively by the RR technique. Unique information on the structure and dynamics of active centers can be extracted from the vibrational spectra. In this section, selected examples are used to illustrate applications of RRS to metalloproteins.

Heme proteins are the classical examples used in RR studies, because of their important biological functions and the possibility of observing high-quality spectra even in dilute solutions. Indeed, the first biomolecular application of RRS was performed on heme proteins by Spiro and Strekas in 1972. The heme group, which consists of the porphyrin ring system and a coordinately bound iron ion (see structure in Figure 1), has intense electronic $\pi–\pi^*$ absorption bands, because of the extended $\pi$ system of the porphyrin ring. The main features of the heme electronic spectrum can be summarized as follows:

- an intense band near 400 nm (Soret or B band, $\varepsilon \approx 10^5$ M$^{-1}$ cm$^{-1}$);
Because coordination of nitrogen atoms from the porphyrin ring to the central metal ion influences the structure of the macrocycle, the observed resonance-enhanced vibrational spectrum contains unique information on the state of the central ion. Vibrations of axial ligands such as CO, CN\(^-\), O\(_2\), F\(^-\), OH\(^-\), and NO can also be studied due to coupling with electronic \(\pi-\pi^*\) transitions.\(^{52,53}\) Excitation within CT transition also results in enhancement of the axial ligand modes.\(^{52}\) The heme group can be considered in the first approximation as a planar structure with D\(_{4h}\) symmetry. Further, if the substituents are treated as point masses, the in-plane and out-of-plane vibrational modes can be represented according to the symmetry shown in Equations (6) and (7), respectively.\(^{54}\)

\[
\Gamma_{\text{in-plane}} = 9A_{1g} + 8A_{2g} + 9B_{1g} + 9B_{2g} + 18E_u \quad (6)
\]

\[
\Gamma_{\text{out-of-plane}} = 3A_{1u} + 6A_{2u} + 5B_{1u} + 4B_{2u} + 8E_g \quad (7)
\]

Because of the presence of the center of symmetry in an idealized heme group, the mutual exclusion principle operates for the Raman and IR selection rules. Only the “gerade” (g) modes are Raman-active, while “ungerade” (u) modes are IR-active. The allowed Raman modes can be recognized in the spectra by different polarization properties: A\(_{1g}\) modes are polarized, B\(_{1g}\) and B\(_{2g}\) modes are depolarized, and A\(_{2g}\) modes are anomalously polarized. It should be noted that the phenomenon of “anomalous polarization” was first observed by Spiro and Strekas for the heme proteins hemoglobin and cyt c.\(^{22}\) The observed spectral pattern depends on \(\lambda_{\text{ex}}\). There is a relationship between the symmetry of resonantly enhanced vibrational modes and the nature of the electronic transition. For a single molecule the Raman intensity \(I_R\) is given by Equation (8)

\[
I_R \sim I_0v_R^4 \sum_{p,s} (\alpha_{ps})_k^2 \quad (8)
\]

where \(I_0\) is the intensity of incident light, \(v_R\) is the Raman wavenumber, and \((\alpha_{ps})_k\) is the polarizability tensor component for the \(k\) transition. The summation is over molecular coordinates \(p\) and \(s\). For RR scattering, in the first approximation the polarizability tensor can be described by two terms as shown in Equation (9).

\[
(\alpha_{ps})_k \approx A + B \quad (9)
\]

Depending on the nature of the electronic transition, term \(A\) or \(B\) dominates. The main features of terms \(A\) and \(B\) can be summarized as follows.

- **Term A** is associated with vibrational interactions with the excited electronic state through Franck–Condon overlapping and usually is a leading contributor to RR intensity. Fundamentals, overtones and combination bands of totally symmetric modes dominate in the spectra. For the heme group this resembles excitation within the \(B\) band and resonance enhancement of A\(_{1g}\) modes and overtones.

- **Term B** is associated with the vibronic coupling of one resonantly excited state to another excited state. As a result, fundamental transitions of non-totally symmetric vibrations are resonantly enhanced. This is often the case when excitation is within a weakly allowed electronic transition which is vibronically coupled with a strong electronic transition. For the heme group this resembles excitation within \(Q\) bands and resonant enhancement of B\(_{1g}\), B\(_{2g}\) and A\(_{2g}\) modes.

Thus by choosing the appropriate \(\lambda_{\text{ex}}\), the A\(_{1g}\) or B\(_{1g}\), B\(_{2g}\) and A\(_{2g}\) modes can be investigated separately, considerably simplifying the interpretation. In real biological systems the symmetry of the heme group is distorted from the idealized D\(_{4h}\) as a result of asymmetric substitutions and deformation of the planar heme structure due to interactions with the protein matrix. Indeed, many in-plane IR-active \(E_u\) and out-of-plane deformation modes have been observed in cyt c RR spectra due to the protein-induced distortion of the heme group.\(^{81}\) When assignment of the RR spectrum is performed, unique information on the state of the heme metal ion can...
be derived by analyzing certain marker bands. A typical RR spectrum from a heme group excited within the B electronic band is presented in Figure 8. Totally symmetric $A_{1g}$ vibrations dominate in this spectrum. Representative marker bands at different states of the heme iron ion are summarized in Table 5. Three main reasons are responsible for the sensitivity of the high-frequency in-plane stretching modes to the state of the Fe ion.\(^{(56)}\)

- The frequency of the C–N and C–C stretching vibrations of the heme group depends on the electron density on the antibonding $\pi^*$ orbitals of the porphyrin ring. Higher electron density weakens the order of C–C and C–N bonds, and as a result the frequency decreases. Transition from Fe$^{3+}$ to Fe$^{2+}$ increases electron occupation on $\pi^*$ orbitals and can be recognized by the lowering of frequency (Table 5). On the other hand, all chemical effects causing withdrawal of the electrons from $\pi^*$ orbitals cause increases in frequency. Such effects refer to the axial ligation of the $\pi$ acid ligands as CO, NO and $O_2$.

- Stretching frequencies of the porphyrin ring depend on the core size of the porphyrin cavity. The core size depends on two factors: the spin state of the Fe ion, and the coordination number (CN). In the high-spin (HS) state two antibonding $d$ orbitals of the Fe ion contain an electron and the porphyrin ring cavity is expanded compared with the low-spin (LS) state, where the antibonding $d$ orbitals are empty. Expanding the core size decreases stretching frequencies (Table 5). The CN of the central Fe ion influences the core size as follows: in the 6C state the Fe ion is located in the heme plane, while in the 5C state the central ion is dislocated from the heme plane towards the fifth ligand. Such a dislocation decreases the core size and as a result, stretching frequencies increase (Table 5).

- Twisting and tilting of Pyr rings in the heme group form the idealized plane structure induced by the protein matrix.\(^{(56,81)}\)

The axial ligation of the heme group can be studied not only through the high-frequency stretching vibrations of the porphyrin ring, but also directly by analyzing the stretching $\nu(M-AB)$, bending $\delta(M-A-B)$ and internal $\nu(A-B)$ modes (Figure 9) of two atomic $AB$ ligands bonded with the metal ion $M$. Such modes were observed in RR spectra excited within the $B$ electronic transition.\(^{(52,53)}\) Important structural information about the bonded $AB$ ligand, including the angle $M-A-B$ and the strength of the $M-A$ bond, can be derived from such studies.\(^{(52,53)}\)

The RR spectra of heme proteins can be observed because of $\pi-\pi^*$ electronic transitions in the porphyrin

system. A different resonance enhancement mechanism in the Raman spectra operates for other metalloproteins, where the metal ion is directly ligated to the protein amino acid residues. Interesting examples for vibrational spectroscopy are the “blue copper” proteins (plastocyanin, Az, stellacyanin and others). The biological function of these proteins, electron transport, is closely related to the geometry of the active site. The structure of the Cu active center in Az can be described as trigonal-bipyramidal (Figure 10). Three strongly bonded ligands, namely the S atom of Cys, and two N imidazole ring atoms from His groups, are arranged in planar trigonal configuration. Two weakly bonded ligands, the S atom from methionine and the O atom from the peptide carbonyl of Gly, lie in the axial position with respect to the trigonal plane. The axial ligands turn the geometry from trigonal to trigonal-bipyramidal. Such a structure is a compromise between the tetragonal geometry usually observed for Cu(II) coordination compounds, and the tetrahedral arrangement characteristic of the Cu(I) compounds, and is believed to be responsible for the fast electron-transfer rates typical for blue copper proteins. In the Cu(II) oxidation state these biomolecules exhibit intense electronic absorption bands around 600 nm assigned to the electronic S(Cys)(π) → Cu(II)(d_e−p) CT transition. The RR spectrum produced by the excitation within this transition consists of several intense bands in the low frequency region (200–500 cm⁻¹), where metal–ligand vibrational modes are expected (Figure 10). Because the electronic transition involves CT from the S(Cys) to Cu(II) ion, the Cu–S bond properties are considerably affected by the absorption, and resonant enhancement in the Raman spectrum is concentrated on vibrations of the Cu–S bond. However, not one but several clear bands are observed experimentally. The origin of the bands has been discussed extensively.\(^\text{56,58,83,84}\) In the earlier studies these bands were attributed to vibrations of Cu–N and Cu–S bonds.\(^\text{83}\) Later, strong coupling between stretching v(Cu–S) and deformation δ(SCC) vibrations from the Cys moiety was suggested to explain the observed lower isotopic \(^{63}\)Cu → \(^{65}\)Cu frequency shift in stellacyanin compared with the value predicted by normal coordinate analysis.\(^\text{84}\) Recent extensive isotopic substitution experiments\(^\text{39,56,58}\) (Table 6) provide evidence that all the bands observed in the 200–500 cm⁻¹ frequency range are generated by stretching vibrations of the Cu–S(Cys) bond dramatically coupled with deformations of the Cu–S–C₅–C₆–N moiety. Multiple shifts induced by all \(^{14}\)N → \(^{15}\)N substitutions demonstrate the participation of the remote N atom of the Cys linkage.

\(^a\) Data from Andrew et al.\(^\text{39}\)
in the coupling phenomenon (Table 6), because no isotopic shifts were observed with labeled N atoms of the imidazole ring in mutant Az.\(^{(39)}\) Experiments with engineered active sites in mutant Az proteins\(^{(85)}\) revealed the sensitivity of the \(\nu(Cu–S)\) frequency to the length of the Cu–S(Cys) bond and thus to the geometry of the active center. The highest frequency, in the vicinity of 430–405 cm\(^{-1}\), corresponds to the trigonal coordination (Figure 11). Weak axial interactions by the \(L'\) ligand cause a slight reduction in frequency. As bonding between the Cu ion and the \(L'\) ligand becomes stronger, and the geometry of the active sites changes through tetrahedral to tetragonal, the \(\nu(Cu–S)\) frequency undergoes a further reduction to 320–300 cm\(^{-1}\) in the pure tetragonal arrangement. As happens frequently with Raman studies of biological molecules, the extended coupling observed between vibrational modes and \(\nu(Cu–S)\) frequency–structure correlations goes far beyond the problems of blue copper proteins and has an impact on the vibrational spectroscopy of coordinated compounds in general.

### 6.3 Nucleic Acids

Applications of RS for the analysis of nucleic acids have been increasing rapidly since the pioneering work of Lord and Thomas in 1967.\(^{(86)}\) Excellent reviews of this extremely complex field are available.\(^{(60–62)}\) Several different and powerful Raman techniques, such as nonresonant RS,\(^{(60–62)}\) UV/RR,\(^{(49,87)}\) SERS,\(^{(32)}\) and ROA,\(^{(28)}\) have been applied in this field, providing different structural flavors for these biomolecules. Excitation in the UV region holds several advantages.\(^{(87)}\)

1. The overall spectrum is simplified, because only the vibrational modes from heterocyclic components of nucleic acids (purine and pyrimidine bases) are preferentially enhanced.
2. The relative intensity of bases depends on \(\lambda_{ex}\), and thus monitoring of particular bases becomes possible. For example, the guanine (G) and adenine (A) residues can be followed selectively using excitation at 250 and 240 nm.\(^{(87)}\)
3. Some modes (for example the \(\delta(NH_2)\) mode which is important in H-bonding studies) which are heavily overlapped with conventional excitation can be observed using the UV/RR approach.\(^{(87)}\)

Recently, a powerful new Raman technique called vibrational ROA was introduced in the field of nucleic acid studies by Bell et al.\(^{(28)}\) The ability of the technique to provide new structural information on conformations of the sugar ring and phosphate backbone has been demonstrated.

The large number of Raman studies on native nucleic acids as well as on model compounds has led to the identification of certain marker bands whose frequency or intensity are sensitive to the structure. In this section we will show what kind of information about nucleic acids can be extracted from the Raman approach. We will try to briefly describe the physical mechanisms leading to the sensitivity of certain Raman modes to the structure and interactions of nucleic acids. Starting from the description of known marker bands we will demonstrate how this method works to solve more practical problems related to interactions of nucleic acids with drugs and proteins.

Four important kinds of information can be extracted from RS studies:

1. H-bonding between bases;
2. noncovalent interactions between bases (base stacking);
3. structural conformations;
4. intermolecular interactions of proteins, drugs, and metal ions with nucleic acids.
In order to understand the complex vibrational spectra of nucleic acids, the lower molecular weight building blocks must be considered first. Nucleic acids are composed of nucleotides. The main components of nucleotides are a heterocyclic base, a sugar, and a phosphate group. Strong features from heterocycles and bands from symmetric vibrations of the phosphate group dominate in the Raman spectra of nucleic acids. Consequently, only those bands will be considered in this section. Characteristic vibrations of the main groups of nucleic acids as well as important marker bands are summarized in Table 7. Interpretation of the spectra is based on isotopic H/D, ¹⁴N/¹⁵N, and ¹⁶O/¹⁸O substitution, comparison with model compounds, normal coordinate analysis, and application of the UV/RR approach. H-bonding interactions can be followed by RS only if certain vibrational modes are concentrated on the motions of atomic groups involved in the bonding. The possible sites for H-bonding interactions are the NH and NH₂ donor groups and C=O and N acceptor groups in base residues as well as oxygen atoms of the phosphate group. Because protons of donor groups are easily exchangeable by deuterons, vibrations of these groups can be unambiguously distinguished by frequency shifts upon H₂O/D₂O solution exchange (Table 7). The strength of the UV/RR approach should be mentioned in this context. While bending vibrations of NH₂ groups (δNH₂) were not resolved using visible excitation, these modes become prominent for A, cytosine (C), and G bases with UV-excited spectra (Table 7). Vibrations of carbonyl groups (νC=O) occur in a rather narrow frequency range (1650–1700 cm⁻¹) and differentiation between C₂=O and C₄=O modes in thymine (T) and uracil (U) bases was performed by ¹⁸O labeling and exploring the high sensitivity of the intensity of the bands associated with (stacking) can be followed effectively by UV/RRS. In this case changes in intensity of the bands associated with the vibrations of purine and pyrimidine rings are monitored. Briefly, the mechanism can be described as follows: stacking of heterocyclic rings suppresses ε of the electronic absorption transition in the UV region. Because the RR enhancement is proportional to ε², the corresponding intensity of UV/RR bands markedly decreases. For example, the intensity of the breathing motion of the imidazole ring at 730 cm⁻¹ in an A base residue decreases upon stacking (Table 7). The third important issue for molecular biologists, where the Raman technique can be valuable, is the structure of nucleic acids. The double helix structure is flexible and several conformational forms labeled as A, B, C, and Z were distinguished. Coupled X-ray diffraction (XRD) and Raman studies led to the elucidation of structural conformation marker bands (Table 7). The conformational sensitivity of

the imidazole ring breathing modes at 730 and 679 cm⁻¹ observed for A and G base residues (Table 7) arises from the orientation effects around the N–R bond. From two observed symmetric phosphate stretching bands, the vibration of bonded oxygen atoms (ν₃PO₂) located at 740–850 cm⁻¹ is the most sensitive marker band of structural conformations, due to the influence of rotation around the R–O⁻ bond on the frequency. The characteristic vibrations of different structural conformers useful for Raman examinations are summarized in Table 8.

Next, application of RS for the analysis of intermolecular interactions between nucleic acids and drugs, proteins or metal ions will be considered. The H-bonding marker bands and vibration of exposed oxygen atoms from the phosphate group (ν₃PO₂) are usually affected by ligand binding. The power of vibrational spectroscopy (Fourier transform infrared (FTIR) and RDS) was recently demonstrated by analysis of drug (aspirin) interactions with DNA. Upshifts in Raman frequencies indicated that at low drug concentrations, aspirin binds through the three main sites in DNA:

1. the phosphate backbone PO₂ group (ν₃PO₂ shifted from 1093 cm⁻¹ in the free state to 1095 cm⁻¹ upon binding);
2. the A N₇ atom (bands at 1342 and 1304 cm⁻¹ shifted to 1344 and 1306 cm⁻¹);
3. the T O₂ atom (band at 1661 cm⁻¹ shifted to 1670 cm⁻¹).

The Raman investigations of binding between the model dinucleotide compound and protein led to the identification of specific binding sites. In this work UV-excited (240–250 nm) RR spectra have shown the interaction of protein ribonuclease with dinucleotide through H-bonding involving the particular N₃ atom in the C base residue. The marker band at 1526 cm⁻¹ was found to be specifically upshifted in bonded dinucleotides (Table 7). Formation of complexes between nucleic acids and proteins was extensively investigated by Benevides et al. Specific marker bands for bonded DNA were recognized. Interactions of drugs (at low concentrations) with DNA can be effectively examined through the SERS approach.

The potential of the SERS technique in analysis of components of nucleic acids at the trace level was also demonstrated. RNA and DNA bases were successfully detected in real time in a combined SERS–flow injection analysis (FIA) system. Figure 12 demonstrates the sensitivity of the SERS technique. Characteristic bands from the adenosine base can be easily recognized after a 50-µL injection of solution containing as little as 800 pmol of biomolecules. In

addition to the sensitivity, the reproducibility is also impressive and encouraging.

6.4 Lipids and Biomembranes

Lipid bilayers are the general components of biological membranes and serve as a matrix for proteins. RS has proved to be valuable in providing information on phase transitions and order in lipid bilayers as well as on interactions of lipids with membrane perturbants such as proteins or drugs.63–66 In this section two main problems will be considered:

1. the relationship between lipid bilayer order parameters and Raman marker bands, and
2. perturbations induced in the lipid structure by drugs and proteins.

Table 9 summarizes the phospholipid characteristic vibrations and marker bands useful in the structural analysis of lipid bilayers. The structure of a typical phospholipid, dipalmitoylphosphatidylcholine (DPPC), is also shown. Three order parameters, $I_{2935}/I_{2880}$, $I_{2850}/I_{2880}$, and $I_{1088}/I_{1130}$ have been shown to be useful for monitoring the self-organization of lipids, the main elements of membrane structure. This is because the C–N stretching (2800–3000 cm$^{-1}$) and C–C skeletal (1000–1200 cm$^{-1}$) modes are sensitive to the intermolecular (between chains) and intramolecular (within chain) interactions to a different degree. While C–C skeletal stretches reflect only the changes in $\psi$T/G conformation (intramolecular order), the C–H modes are sensitive to both $\psi$T/G (intramolecular) and lateral chain–chain (intermolecular) interactions. Phase transitions between the bilayer gel and the liquid crystalline phase can be sensitively monitored using the dependence of the appropriate order parameter (Table 9) on the temperature.63–65

Interactions of polypeptides, proteins, nucleic acids or drugs with lipid bilayers induce changes in the bilayer structure affecting marker bands and providing the possibility of studies by RS.65 Depending on the interaction type, ordering or disordering of lipid bilayers was observed. For example it was established that the charged polypeptide poly-L-lysine raises the transition temperature of zwitterionic phosphatidylcholines by 7°C, suggesting that the interaction is stronger in the gel phase than in the liquid crystalline phase.65 By contrast, an intrinsic membrane protein, the coat protein of filamentous phage viruses, lowers the phase transition of lecithin bilayers. In general, Raman data indicate that intrinsic membrane proteins, interacting over a large surface area with acyl chains, induce a higher number of G conformers within chains and lower the mobility of the chains. On the other hand, the extrinsic proteins interact mainly through the charged groups and in general increase the transition temperature.65

6.5 Dynamics in Biomolecules

Understanding the specific functions of biomolecules requires that the dynamics of conformational transitions and bonding with transient species are described in molecular detail. That is, techniques sensitive not only to the structure of biomolecules but also having nanosecond or even picosecond time resolution must be applied. Recent progress in laser technology and optical detection has enabled time-resolved Raman (TR2) spectroscopy to become one of the most powerful methods in the study of ultrafast biomolecular events.\(^{38,67–69}\) Due to the intrinsic weakness of the Raman process, the resonance-enhancement phenomenon is usually explored in such studies, and the technique is labeled as TR3 spectroscopy. There are two essential steps in TR3 experiments: initiation of the process, and monitoring of the process. Based on the process initiation protocols, the following methods can be distinguished:\(^{67}\)

1. rapid-mixing methods;
2. light-initiated methods using continuous wave (CW) lasers:
   - rapid-flow method
   - spinning-cell method;
3. light-initiated methods using pulsed lasers:
   - single-pulse method
   - dual-pulse method (“pump” laser beam for initiation of the process and a different wavelength “probe” beam for process monitoring).

This TR3 strategy was successfully applied to numerous biological systems, including heme enzymes, photosynthetic reaction centers, and visual pigments.\(^{67}\) In the case of heme enzymes, the fast light-driven de-ligation of the CO adduct of the Fe(II) form serves as the initiation step. The following structural transformations of the protein matrix can be examined using either a probe beam at Soret absorption wavelengths to monitor the \(\nu(\text{Fe}–\text{N(His)})\) mode evolution, or a UV-probe beam to monitor changes in aromatic amino acid residues by exploring the UV/RR phenomena. The relationship between the structure of the protein matrix and the ligation state of the heme group in hemoglobin was demonstrated by Rodgers et al.\(^{93}\) In this work the photolysis of hemoglobin-bound CO was initiated by the 419-nm laser pulse and the delayed 230-nm pulse served for the selective excitation of the transient UV/RR spectra from the Trp and Tyr residues in protein. Similar transient UV/RR spectra of the aromatic amino acid residue Tyr excited using a 240-nm probe beam were successfully applied for the monitoring of millisecond or even nanosecond structural changes in Bacteriordopsin initiated by the 515-nm pump beam.\(^{94}\) As another interesting example to illustrate how the dynamics of biomolecules can be seen through RRS, the folding and unfolding reaction of cyt c will be considered briefly. Recently, a rapid solution-mixer with a 100-μs time resolution was coupled with RRS, providing the ability to monitor the folding/unfolding dynamics of cyt c with sub-millisecond resolution.\(^{95}\) The initiation of folding was achieved by rapid dilution of denaturant-unfolded protein with an excess of buffer solution. The low-frequency mode (at 394 cm\(^{-1}\)) of the ferrous heme form associated with the folding reaction.\(^{95}\) In the native folded state this band is intense, because of the twisting and tension of the heme and the polypeptide \([\delta(C_C–C_C–S)]^{91}\) served as the folding/unfolding marker band. Figure 13 demonstrates the development of the low-frequency spectrum during the folding reaction.\(^{95}\) In the native folded state this band is intense, because of the twisting and tension of the heme group induced by the surrounding polypeptide. This band virtually disappears in the unfolded state, due to the more planar structure of the heme group. It is clear

\[\text{Figure 13} \quad \text{Time evolution of the low-frequency RR spectra of cyt c following the initiation of folding. The ferrous CO-bound form of the protein was unfolded in 7.0 M guanidine hydrochloride (Gdn-HCl) and refolded in 0.7 M Gdn-HCl at neutral pH. The insert is the decay curve of the unfolded form obtained by monitoring the line at 394 cm}^{-1}. \text{The line at } 491–498 \text{ cm}^{-1} \text{ is assigned as the Fe–CO stretching mode.} \text{Reproduced by permission of American Chemical Society from S.-R. Yeh, S. Han, D.L. Rousseau, Acc. Chem. Res., 31(11), 727–736 (1998).}\]
from Figure 13 that microscopic details of the folding reaction can be monitored in real time by RRS.

6.6 Raman Microscopic Analysis of Biological Systems

The structural sensitivity inherent to vibrational spectroscopy is combined with spatial resolution of 0.1–2 µm in MRS. Such a combination makes the MRS technique extremely attractive for applications in molecular biology such as analysis of cell components, drug distribution, or identification of the constituents of the cell membrane. Recent introduction of UV/RRS in this field has considerably increased the selectivity and sensitivity of the MRS technique for molecules absorbing in the 180–300-nm region. There is a growing interest in the application of the MRS approach to in vivo analysis of biomaterials.

Caspers et al. have studied human skin in vitro and in vivo using a confocal Raman microspectrometer. The inverted microscope principle shown in Figure 14(a) was used for the in vivo Raman measurements. A CaF2 window serves as support for the sample of interest. The required depth with the 9-µm resolution was achieved by translating the objective vertically. It was possible to record Raman spectra with 0-µm depth directly from the skin. Differences in several spectral regions (1640–1680 cm⁻¹ amide I region; 1240–1300 cm⁻¹ amide III region; bands at 1415 cm⁻¹, 855 and 880 cm⁻¹) can be easily identified from Figure 14(b) by comparing Raman spectra from different places on the skin. Variations in human moisturizing factors and lipid contents were suggested as possible reasons for some observed spectral variations. These results demonstrate the possibility of obtaining noninvasive vibrational spectra from living skin that contain information about the composition and structure of different places and layers of the skin.

7 FUTURE DEVELOPMENTS OF RAMAN SPECTROSCOPY

Advances in laser technology will make UV lasers cheaper. Because electronic systems of important biological structures such as bases of nucleic acids, aromatic amino acid residues, and peptide groups have electronic transitions in the 180–300 nm range, the applications of UV/RRS will rapidly expand.

There is some hope that progress in the preparation of more reproducible and stable surfaces for SERS will expand the application of this technique to monitoring traces of biomolecules in more applied investigations.

With a further reduction in the price of combined FTR/FTIR instruments, routine characterization of biosamples using vibrational spectra, especially at higher concentrations, will become common.

The progress in quantitative analysis by RS is connected to the development of simple sensitivity-calibration procedures and the evolution of detection systems.

The combination of highly sensitive Raman techniques (RR, UV/RR and SERS/SERRS) with the submicrometer spatial resolution ability of MRS is encouraging,
and holds promise for the wide expansion of vibrational spectroscopy to the analysis of single living cell components, leading to direct biomedical applications. However, problems with the laser-induced photodegradation of the sample will be apparent in this field.

8 COMPARISON WITH OTHER SPECTROSCOPIC METHODS

In this section the structural information and sensitivity of RS will be compared with IR, ultraviolet/visible (UV/VIS) absorption, and Fl techniques. An important feature of modern RS is the variety of techniques for exploring the Raman phenomenon (Table 1). Thus in making any comparison the technique will be specified. We will focus our attention on RS and IR techniques.

8.1 Structural Information

The main disadvantages of UV/VIS and Fl techniques are their lack of structural sensitivity. In contrast, two vibrational spectroscopic techniques, RS and IR, are able to provide rich structural information on the molecular systems. The resolution of vibrational spectroscopies is several orders of magnitude higher than for UV/VIS or Fl. For this reason we will concentrate on a comparison of the IR and RS methods. The first advantage of RS is the weak Raman scattering from water, in contrast to IR absorption. Therefore biomolecules can be studied in their natural environment. Secondly, resonance and surface-enhancement effects are possible for RS, providing the possibility of selectively monitoring the structure of certain molecular groups or adsorbed species. This is extremely important for large molecular systems such as biomolecules, due to interpretation problems. Third, \( \rho \) measurements provide an elegant way for assigning the vibrations according to their symmetry. Fourth, Raman spectra can be easily recorded over a wide frequency range \( (100–4000 \text{ cm}^{-1}) \), in contrast to IR spectra. Thus structurally important, low-frequency, metal–ligand vibrations can be studied using RS.

8.2 Sensitivity

The main disadvantage of RS compared with IR for analytical applications is the difficulty in establishing the analyte concentration from the Raman intensity, because the value of the Raman cross-section of an analyte molecule is usually unknown or is difficult to estimate. In addition, Raman intensities depend on many factors. For this reason internal standard methods are usually employed in RS. The sensitivity of IR spectroscopy, for example in studies of protein–ligand binding, is of the order of \( \sim 10^{-3} \text{M} \) (by monitoring the ligand internal mode); this is higher than nonresonance RS. In the case of RRS, however, the same protein–ligand systems can be monitored by low-frequency vibrations at concentrations in the order of \( \sim 10^{-5} \text{M} \). The most sensitive technique, used for the determination of trace levels of fluorophores or even single molecules, is Fl spectroscopy. However, single molecules have also been detected recently using SERS and SERRS. High sensitivity and also structural specificity were evident from these experiments.

Recently the sensitivity limits for the analysis of proteins with nonresonant RS and RDS were considered using a CCD detection system and an axial transmissive Raman spectrometer. Good spectra were collected from 100-µM concentrations of protein. Finally, as can be seen from Figure 12, it is possible to detect adenosine at the 800-pmol level in a 50-µL sample using the SERS technique.

ACKNOWLEDGMENTS

The author would like to thank Dr Adolfas Gaigalas, Dr Vincent Vilker, and Dr Vytas Reipa from the Bioprocess and Engineering group at NIST (Gaithersburg, USA) for stimulating discussions and support during his stay at NIST and later. He also thanks Dr Rimas Jakubenas for useful discussions and assistance in preparing figures.

1 INTRODUCTION

The ultimate goal of sensitivity in analytical chemistry is single molecule detection, characterization and particularly the study of reactions of individual molecules with each other. The era of this grade of perfection of analytical chemistry has dawned with the end of the passing millenium and certainly the new millenium will become the time of single molecule physics, chemistry and biology. By the end of 1999, in addition to a number of reviews, special issues of regular journals[1–4] on single molecules and a book[5] are available in the literature.

2 HISTORY

One of the first single molecule experiments (1961) in analytical biochemistry is the study of the reaction of a single β-galactosidase molecule held in a microdroplet.[6] Widespread applications became possible in the 1980s, with the advent of near-field microscopies which allowed imaging, for example, of the orbitals of benzene molecules.[7] It came as a surprise that these micrographs (probably nanograph would be the better expression) revealed a threefold symmetry rather than a sixfold symmetry as one might have expected from the Kekulé formula. Later, individual atoms and molecules could be manipulated with the tips of such scanning microscopes (for these microscopy techniques see below). These pure detection techniques did not yet allow spectroscopy, since they were monochromatic. Color and thus spectroscopy in the sense that it is typically used by the analytical chemist were not yet widely used. This problem was alleviated by the advent of the near-field scanning optical microscope. Then it became possible to use the
wavelength of an individual molecule which had already been exploited in bulk analytical or physical chemistry to obtain spectral information. The biggest surprise was the finding that normal – though high quality – fluorescence microscopes could be used for single molecule analysis. This was thought to contradict the Abbe criterion which states that the resolution of a classical far-field microscope is not better than 50% of the wavelength of the light used for illumination (0.5 μm for green light). The mistake of the sceptics was that they confused resolution with reproducibility of localization. When the molecules were prepared with sufficiently small concentration onto a surface, they had an average distance of several micrometers from each other: they no longer had to be spatially resolved, they just had to be visualized. Visualization of individual molecules is possible down to sizes of a few nanometers (see for example page 274 of Greulich[8]). The price one has to pay is that the molecules appear too large, but for many applications this drawback is acceptable. The classical fluorescence microscope has two significant advantages compared to the above-mentioned near-field microscopies. It is fast (standard temporal resolution is video frequency, 40 ms, and even this can be speeded up), i.e. the dynamics of molecules and reactions becomes experimentally accessible and preparation techniques can be easily adapted from bulk analytical methods. Thus, with the advent of classical fluorescence microscopy the path was paved to studying real single molecule reactions. Some studies dealt with small reactions such as the catalytic oxidation of CO on platinum 111. Here it turned out that the individual molecule reaction just reflected what was known from bulk. A different situation was expected for biomolecules: since theoretical knowledge of protein structures had predicted that all individual enzymes of a species would differ slightly but distinctly from each other, it was no surprise that they revealed different reaction rates.[9] A particularly attractive target for single molecule studies is the DNA molecule. DNA is so variable that it is not possible to synthesize one copy of each possible DNA molecule only 120 basepairs in length (a typical gene would be much longer). The mass of the universe would not suffice (see for example page 161 of Greulich[8]). Due to this virtually unlimited variability, analysis of DNA single molecules, unlike conventional genome-megaprojects, may finally provide full information on DNA as a molecular individuum.

3 PREPARATION AND HANDLING OF SINGLE MOLECULES

Two types of single molecule solutions are interesting for single molecule research: highly diluted solutions of small molecules (single chromophores) and, on the other hand, biological macromolecules stained with a large number of chromophores.

3.1 Microfluidics for Single Molecule Handling

Typical bulk dye solutions are millimolar to micromolar. A solution with one molecule in the typical volume of 1 fL which is used in single molecule research corresponds to 10^{15} mol L^{-1} or approximately a nanomolar solution. These small concentrations can be obtained by conventional serial dilution. In order to prevent loss of single molecules to vessel walls, suitable materials are helpful, for example hydrophobic ones for hydrophilic molecules and vice versa. A problem is to set the time point for a reaction start. One approach is to premix the reaction partners, dilute them subsequently, transfer them to a surface and then observe the reaction. With such a strategy, the first minutes of the reaction are lost and therefore only slow reactions can be observed. An alternative approach is to bring the reaction partners onto a surface in separate nanodroplets and to start the reaction by fusing the latter at a preselected time. Here, the reaction can be observed a few seconds after mixing.

3.2 Preparation of Single Biological Macromolecules

A completely different approach is possible when biological macromolecules such as DNA, microtubules or actin filaments are involved. Such molecules can be coupled to micrometer sized polystyrene or silica spheres which act as a sort of handle. They can be handled micromechanically, or, more gently and precisely, by optical tweezers.[9] One successful strategy to start a reaction of such a macromolecule with a reaction partner is to use caged compounds: for example, many enzymes acting on DNA require magnesium. When the latter is present as a caged compound (and thus is inaccessible for the enzyme) the reaction cannot proceed. When the caged compound is disrupted by irradiating it with ultraviolet light, the magnesium is released and the reaction starts immediately.

3.3 Laser Micromanipulation for Handling of Individual Macromolecules

An interesting tool for handling of individual macromolecules are optical tweezers: a continuous infrared laser of moderate power, which is focused in a microscope to the theoretical (diffraction) limit. Light pressure and gradient forces push microscopic objects in the focus of the laser. By moving the focus, these objects can be moved along complex trajectories. Since only forces exerted by light are acting, no sticking of individual molecules to microtools or disruption by the latter occurs.
4 INTERACTION OF LIGHT WITH SINGLE MOLECULES

A single, light absorbing molecule is a unique quantum system which interacts with the light field. Such an interaction not only allows us to obtain unique information on the molecule, but also on the intrinsic properties of light. For example, a number of important experiments on which quantum mechanics are based only exist so far as “Gedankenexperiment” or have, at most, been experimentally verified only in a disputable way. Surprisingly for many, the famous quantum mechanical version of the double slit experiment is among these unsolved problems. This crucial experiment, where it is assumed that individual photons hit the double slit and interfere with each other or with themselves, has never been performed since it is difficult to produce single photons. In most cases wavetrains are produced by attenuating a laser, and this is not what the Gedankenexperiment needs. With single molecules one has for the first time the perspective to produce and use individual photons safely.

5 FLUORESCENCE CORRELATION SPECTROSCOPY AS A QUASI SINGLE MOLECULE TECHNIQUE

There are basically two strategies for the observation of single molecules: one may embed them in some sort of matrix and observe them at the surface of a substrate material, or one may study them directly in solution. The latter technique requires extreme dilution of the molecules and simultaneously extreme miniaturization of the observation volume. This has been achieved by investigating solutions of fluorescing molecules with a diffraction limited fluorescence microscope, i.e. in an observation volume of less than 1 fl. Basically, in such experiments the velocity of a molecule migrating through the tiny observation volume is measured. One detects a single molecule in a given volume, and after a preset time of waiting one looks to see if it is still there. Slow particles will be found several times, fast particles will be found only twice or three times. Mathematically, this is described by the correlation function (Equation 1)

$$G(t) = \sum I(t)^* I(t + T)$$ (1)

where T is the waiting time.

$G(t)$ is related to the speed of the molecule which can be used to calculate the diffusion constant of the molecule. The latter can be used to estimate the molecular weight. Such experiments are often used to measure the binding of two individual molecules. This is possible when the two binding partners differ by at least a factor of 8–10 in size, for example the binding of an antigen to an antibody or the hybridization of a small DNA or RNA oligonucleotide to a long DNA or RNA molecule. In such experiments, the smaller binding partner is made fluorescent. One will see the small partner as a fast diffusing object and the complex of small with large partner as a slow object. The correlation analysis not only allows the absolute migrating velocities to be measured, but also the ratio of free to bound molecules, i.e. the binding constants according to the mass action law. Since one needs to measure a number of molecules and molecular complexes to obtain such binding constants, fluorescence correlation spectroscopy is not a true single molecule technique, but it is a technique for very small concentrations. True single molecule techniques can be based on microscopies as described in the following.

6 MICROSCOPY OF SINGLE MOLECULES

6.1 Near-field Microscopies

The near-field microscopes all work according to a common basic principle: a sort of ultrafine stylus scans an object matrixwise and subsequently assembles an image from the data it has obtained. This data assembly takes some time and therefore the temporal resolution of these microscopes is limited to seconds or somewhat below seconds. In turn, the spatial resolution is better than with any other tool available to the analytical chemist or biochemist. The reason for this is that the stylus comes very close to the object under observation. It is the same principle as the stethoscope of a medical doctor: there, acoustic waves of a beating heart with wavelengths of meters can be exploited to localize the heart with an accuracy of centimeters. Therefore, the optical version of the near-field microscopes, the SNOM (scanning near-field optical microscope), has also been called the optical stethoscope. It has a typical spatial resolution of 60 to 80 nm and can be used as a highly localized spectroscope. The second near-field microscope used in the analysis of single biomolecules is the atomic force microscope (AFM). Here, a mixture of van der Waals, electrostatic and other forces is used to detect the molecule. Since these are all short range forces, one has to get closer to the molecule under observation and the spatial resolution is better than with the SNOM for ideal (hard) objects in the subnanometer range. The near-field microscope with the best resolution is the scanning tunneling microscope which, under favorable conditions, can detect submolecular structures as mentioned already in the historical overview. It needs electrically conducting objects.
6.2 Very Highly Sensitive Fluorescence: Dyes and Detectors

The near-field techniques for the detection of single molecules often require specific preparation protocols. Also, the tip of the detecting stylus is very sensitive and can easily break. The typical practical lifetime of such tips are hours or days at most. Therefore, near-field microscopies may easily become time-consuming and expensive. This may be one reason why classical far-field microscopy has got its chance in single molecule analysis. Here, light is the carrier of information and comparatively gentle interactions can be used to study individual molecules. A disadvantage is that only molecules with a significant fluorescence yield or nonfluorescing molecules after labeling with a fluorescence dye can be investigated. Among biomolecules, NADH, flavines and other natural compounds occurring in biological cells are used. For biological macromolecules, a large number of fluorescing dyes is available which are known not, or only moderately, to modify the macromolecule’s function. Many of these dyes have been developed to match with their absorption maximum the working wavelength of standard lasers.

Detecting single molecules by a fluorescence microscope is not so much a problem of the number of emitted photons. Since a molecule can, in principle, emit a light quantum every 10 ns, up to 100 million quanta might be expected from a single molecule per second. Two problems hamper this process: first, a dye molecule will decay after a few hundred up to a million cycles of excitation and emission into nonfluorescing derivative. Second, in order to excite a dye molecule at typical concentrations (see above), some $10^8$ photons will pass the detection volume. In other words, one has a large number of unwanted photons per useful photon for the detection of the molecule. Optical filtering techniques are not completely sufficient to identify the useful photon. This is the major challenge for classical light microscopy in single molecule analytics. Part of these problems may be overcome by replacing classical fluorescence dyes by nanocrystals or quantum dots. These are nanometer sized clusters of, for example, zinc sulfide capped cadmium selenide.$^{(12)}$ Their absorption and emission behavior is solely determined by their size: small clusters are blue, larger ones are red. An advantage of these quantum dots is their very good absorption and emission behavior; a disadvantage is their bulkiness.

6.3 Classical Far-field Microscopy for High Temporal Resolution

In spite of these problems, classical far-field microscopy is attractive since it provides high temporal resolution. When a fluorescence microscope is equipped with a standard TV CCD camera, one can obtain 25 images per second. This corresponds to a temporal resolution of 40 ms. Special cameras are much faster and millisecond resolution is easily available when one is willing to go a step beyond standard CCD recording. For low level light, as in single molecule research, cooled CCD cameras integrating over several image frames can be used, but then the temporal resolution is decreased correspondingly. When extreme sensitivities at high temporal resolution are required, single photon counting cameras are available. These are in principle arrays of microphotomultipliers, often with $250 \times 250$ pixel elements. In almost all cases the reduced (as compared to standard CCD cameras with $700 \times 500$ pixels) image size is completely sufficient, since single molecule observation requires only parts of a full visual field in a light microscope. For an overview on such cameras see Pilarczyk.$^{(13)}$

Color information can be added by using a true color camera but they do not usually have the sensitivity described above. More efficient is the use of optical filters. Fast switching filter wheels and computer programs for exactly overlaying the different colors are available on the market.

7 SINGLE (NONBIOLOGICAL) MOLECULE SPECTROSCOPY

Since the energy states in molecules are not indefinitely sharp, absorption and emission lines have a nonzero width. From quantum mechanics, one can relate these widths with lifetimes of a specific energy state and with other properties of a molecule. The shape of such a line can be described by a Lorentzian curve. Line widths in bulk experiments detect an average over many slightly differing molecules – they are “inhomogeneously broadened” – i.e. they are much wider than the informative Lorentzians. Therefore, the advent of single molecule techniques represents a milestone for molecular spectroscopy. Even time resolved fluorescence studies on single molecules$^{(14–16)}$ and three-dimensional imaging are now possible,$^{(17)}$ not only in solid state, but also in solution.$^{(18)}$

7.1 Reaching the Limits of Spectroscopy

One of the first steps towards single molecule spectroscopy was achieved with pentacene or terrylene molecules embedded into a $p$-terphenyl single crystal matrix (see for example chapter 1 in Basche et al.$^{(15)}$). Many of these experiments were performed in the cold. Such experiments showed that very narrow line widths (10 MHz at 1 K) broadened by a factor of 100 when the temperature was increased by only $10^°$ (chapter 2 in Basche et al.$^{(5)}$).
7.2 A Direct View on Quantum Mechanical Properties

One of the probably most convincing single chromophore experiments deals with a central phenomenon of spectroscopy and quantum mechanics. A fluorescing dye molecule absorbs light and, after typically a few nanoseconds, re-emits it at a longer wavelength. Occasionally, by intersystem crossing, it goes into a triplet state. Quantum mechanics predicts that this state lives theoretically forever, in practice microseconds to hours (the latter is known from the phosphorescence of the face of a watch). In bulk experiments this prediction could be verified, but never directly seen. Several groups have now shown this process on the single molecule level: terrylene molecules were embedded in their p-terphenyl matrix and observed over a long period. During most of the time, they absorbed, re-emitted, re-absorbed and so on. Occasionally, they were “off” for a longer period. In some cases, this molecular blinking was attributed to transient oxidation. In other experiments oxidation could be excluded and the blinking was attributed to the quantum mechanic transition into the long lived exited triplet state. As long as the molecule is in this state, no further absorption and re-emission can occur: the molecule remains dark. This is the first direct visualization of a single-triplet transition: for the first time the observer has a direct view on a true quantum system (see chapter 1, page 52 in Basche et al.).

7.3 Magnetic Resonance of Single Molecules

While near-field microscopy and optical far-field techniques represent the major tools for single molecule research, a few additional methods exist. One of the most important of these is the magnetic resonance technique. Usually, nuclear magnetic resonance (NMR) works with radiowaves and electron spin resonance with microwaves. In both cases, the energy per photon is small; one needs many of them to detect a spin and therefore the methods are not sensitive enough for single molecule detection. However, one can also detect the spin resonances optically (optically detected magnetic resonance, ODMR), and then single spin sensitivity can be achieved. This and other improvements of magnetic resonance techniques now allow single spins to be detected and analyzed.

8 SINGLE MOLECULE BIOPHYSICS AND BIOCHEMISTRY

Single molecule techniques are even more important in studies of biological macromolecules. For some biological macromolecules the individual differences are not only interesting for reasons of basic research. Such differences may be important also for health and disease. For example, the malfunction of an enzyme may cause irregularities. Such a malfunction may develop by a sort of evolution and may only gradually turn into a true disease form. Early detection of such changes on the single molecule basis will probably allow early diagnosis and thus may help to prevent the outbreak of a disease.

8.1 Direct Observation of Single Molecule Reactions

The conformational dynamics and cleaving mechanisms of enzymes can be directly observed at surfaces. The action of individual enzyme molecules in solution becomes accessible, for example, when a nonfluorescent substrate is converted into a fluorescent product or vice versa, or when the reaction with nonfluorescent partners can be made visible by a subsequent fluorescence reaction as is general practice in medical diagnosis or in nutrition chemistry. For example, the conversion of nonfluorescing NAD⁺ into fluorescing NADH by individual molecules of lactate dehydrogenase has been observed by this approach. In the two droplet approach as described above, the reaction of some ten molecules has been observed. By the premix technique, quantized reaction rates have been found. The rates were multiple integers of a basic reaction rate. This was interpreted as the reaction catalyzed by one, two . . . up to six enzyme molecules. For this type of study the term “single molecule enzymology” has been coined.

8.2 Nanometers and Piconewtons: Mechanical Properties of Single Macromolecules

The mechanical properties of filamentous molecules can be measured directly with optical tweezers. For this purpose again microbeads are biochemically coupled to the ends of the molecules and then pulled apart either by the stylus of an AFM or by optical tweezers. The force required to elongate such a molecule is measured.

8.3 The Tiniest Motors: Kinesin, Dynein and Myosin

Self driven motion and reproduction are two characteristic features of life. Both depend on molecular transport processes. In many of these processes, either dynein or kinesin molecules travel along rail-like filamentous structures called microtubules. Correspondingly, myosin molecules move along actin filaments. The action of a muscle, for example, results from the concerted operation of thousands of such tiny motors, which in most cases convert the chemical energy of an adenosine triphosphate molecule into motion. Typical single molecule experiments bind the rails (microtubules or actin) to a glass surface of a microscope slide and observe the single, fluorescently labeled motor protein gliding along the rails.
Alternatively, the motors are bound and the filamentous rails are held with double optical tweezers in suspension. When the molecular motor transports the rail, force is exerted on the optical tweezers, which can be measured with piconewton accuracy. Such experiments have shown that the force exerted by single motor proteins is of the order of a few piconewtons and the step width with which it moves along a rail is 8 nm for kinesin and probably also for dynein, while it may range from a few nanometers up to more than 10 nm for native and genetically modified myosin molecules with a different neck region. For kinesin, single molecule experiments under permanent load showed that models derived from bulk data, where permanent load of in vivo processes could not be simulated, cannot be correct. In these experiments, Michaelis–Menten kinetics, a very basic mechanism of biochemistry, could be measured on the single molecule level.\(^{[23]}\) For myosin, per nanometer of a structural part called the neck region, the step width is 0.5 nm.\(^{[24]}\) Similar experiments have been performed with RNA polymerase from \textit{E. coli}. A surprise was that this enzyme exerts a force more than double that of the motor proteins, in spite of the fact that its task is not to generate motion but to read genetic information from DNA into RNA. A possible explanation for this finding is that this enzyme does not read from naked DNA but from DNA complexed with proteins (histones, nucleosomes) and that the force is required to read its way through these obstacles. The RNA polymerase experiments, similar to the kinesin experiments described above, also showed the importance of true single molecule experiments for the elucidation of the basic mechanisms of generation of motion.\(^{[25]}\) Perhaps it is only an experimental curiosity: knots have even been tied into actin molecules.\(^{[26]}\)

### 8.4 Receptor–Ligand Binding on a Single Molecule Basis

The imaging of single molecule diffusion\(^{[27]}\) and the counting of single protein molecules at surfaces represent important steps for limiting the sensitivity analysis of disease processes. This may be binding to hormone receptors or antigen–antibody binding. A technique to count such binding processes has been developed by L"oscher.\(^{[28]}\) Even more detailed are studies on the forces between individual antibodies and their antigens.\(^{[29]}\) The perspective of such studies is not only to learn details on the underlying binding process, but also to develop a force sensing microscope.

### 8.5 DNA as a Molecular Individuum

The unlimited variability of DNA molecules and the resulting need of single molecule studies has already been addressed above. Mechanical properties of individual DNA molecules can be studied for example by stretching them first in a shear flow and then observing by a fast video microscope camera how these filamentous structures collapse into random coils.\(^{[30]}\) When DNA is overstretched, mechanical properties become sequence dependent.\(^{[31]}\) A special double stranded DNA construct, which is overwound and thus supercoiled, can be stretched and thereby denatures locally, i.e. the double strand becomes opened into two single stranded stretches of DNA.\(^{[32]}\) A similar experiment separated two complementary strands of DNA mechanically, whereby obviously the double helix was unwound without prior overwinding. The required separation force is different for GC- and AT-rich sequence elements and thus information on the base composition of a single DNA molecule can be obtained with an accuracy of 100–500 bases.\(^{[33]}\) Since DNA exists in different structural forms, for example B-DNA and Z-DNA with different lengths per basepair, structural transitions can be exploited to construct a nanomechanical device.\(^{[34]}\) Studies on the behavior of single DNA molecules in gels have a quite different motivation.\(^{[35]}\) Here, the mechanism of gel electrophoresis of large DNA fragments is studied.

Of particular interest is the direct observation by light microscopy of DNA cutting, since this is a process occurring in many processes in life sciences. The observation of such reactions in electrophoresis gels has been termed optical mapping.\(^{[36]}\) Phosphodiester bond breaks have been directly observed in a dual beam optical microscope\(^{[37]}\) and the binding of RecA molecules to a single DNA molecule held by double beam optical tweezers was visualized directly in a light microscope.\(^{[38]}\) The enzymatic cleavage of an individual Lambda phage DNA molecule by the restriction endonuclease Apal has been observed.\(^{[39,40]}\) One of the most beautiful single molecule experiments is perhaps the visualization of an RNA polymerase molecule running along a DNA molecule. The processivity of this enzyme can thus be directly seen, without any model assumptions.\(^{[41]}\)

1 INTRODUCTION

VOA is defined as the differential response of a molecule to LCP versus RCP radiation during a vibrational transition. This article describes recent progress in the field of vibrational optical activity (VOA) as a probe of the structural properties of pharmaceutical and biological molecules. A strong emphasis is placed on vibrational circular dichroism (VCD) owing to its more advanced state of development. Raman optical activity (ROA) is included in the first two sections for completeness; other reviews give additional information about ROA.\(^{(1-3,8)}\) The article focuses on the practical aspects of VCD spectral measurement and interpretation. This is supplemented by examples that serve to illustrate the principal areas of VOA application. VCD is defined as the difference in the absorbance of the left circularly polarized (LCP) versus right circularly polarized (RCP) infrared (IR) radiation for a chiral molecule undergoing a vibrational transition. A pair of enantiomers will produce VCD spectra that are equal and opposite in sign and a racemic mixture will have a null VCD signal. VCD can be measured for all kinds of chiral molecules, irrespective of their size. In practice, measurements are often carried out in solution but, with the new advances in instrumentation, it is now possible to measure spectra of solids and mulls. Compared to other optical techniques such as electronic circular dichroism (CD) and IR absorption, VCD is unique because it combines the optical activity property of CD with the rich structural fingerprint region of IR. The discovery and first measurements of VCD occurred in the early 1970s. Although over a dozen practitioners have published close to a 1000 papers since then, it is only recently that VCD instrumentation has become available commercially for nonspecialists. Applications span a variety of fields from chemical and pharmaceutical to biological. The VCD technique can be used for the determination of absolute configuration of small chiral molecules or larger natural products. It can also be used to follow a chiral synthesis both for stereochemistry and for optical purity, and to study the secondary structure of large proteins and small peptides, and the conformation of nucleic acids and sugars. Some recent reports have also shown the unique sensitivity of ROA in the study of viruses and in protein-folding experiments. VOA is now fulfilling its promise of becoming a technique that is broadly used for stereochemical and conformational studies of all varieties of chiral molecules, both natural and synthetic.
occur. For Raman scattering, there is no classical analog, thus ROA is measured as circularly polarized (CP) intensity differences in the incident laser radiation, the scattered radiation, or both. As with CD, VOA is zero unless the sample possesses molecular chirality, either through its constituent chiral molecules or through a chiral spatial arrangement of nonchiral molecules.

1.1 Definitions of Vibrational Circular Dichroism and Raman Optical Activity

There is only one form of VCD as it involves the differential response of a molecule undergoing a one-photon transition. The spectra are typically measured as the difference in the absorbances of a molecule for LCP minus RCP light (Equation 1):

\[
\Delta A(\tilde{v}) = A_L(\tilde{v}) - A_R(\tilde{v})
\]  

where \(\tilde{v}\) is the wavenumber frequency in units of \(\text{cm}^{-1}\). Alternatively, the effects of path length \(l\) and concentration \(C\) may be eliminated by using the absorption coefficient (Equation 2):

\[
\Delta \varepsilon(\tilde{v}) = \frac{\Delta A(\tilde{v})}{lC} = \varepsilon_L(\tilde{v}) - \varepsilon_R(\tilde{v})
\]  

The ROA method is more complex than VCD both experimentally and theoretically. There are four distinct forms of ROA involving CP radiation and an additional four involving linearly polarized light, although the latter are more specialized and will not be discussed further. If we designate the polarization state of the incident laser beam with a superscript and that of the scattered radiation with a subscript, the four forms of CP/ROA can be written as in Equations (3–6):

\[
\begin{align*}
\Delta I_L(\tilde{v}) &= I_R^L(\tilde{v}) - I_L^L(\tilde{v}) \\
\Delta I_R(\tilde{v}) &= I_R^R(\tilde{v}) - I_L^R(\tilde{v}) \\
\Delta I_{II}(\tilde{v}) &= I_R^L(\tilde{v}) - I_L^R(\tilde{v}) \\
\Delta I_{III}(\tilde{v}) &= I_R^L(\tilde{v}) - I_L^R(\tilde{v})
\end{align*}
\]

Here, the intensities are a function of the wavenumber shift of the scattered radiation. The form of ROA given in Equation (3) is the one first discovered and measured since the 1970s. It is called incident circularly polarized (ICP) ROA because only the polarization state of the incident beam is switched between RCP and LCP states. The polarization state of the scattered light is a fixed linearly polarized or unpolarized state. Note that the definition of ICP/ROA is opposite that of VCD with respect to RCP and LCP radiation. This is the result of historical convention, and not the result of any deep underlying principle. In fact, recent work on the theory of resonance Raman optical activity (RROA) has revealed a direct connection between the electronic CD of the resonant state and the observed RROA in which the magnitudes are the same and the sign correlation is opposite owing to the opposite definitions of CD and ROA. The other three forms of ROA involve changing the polarization state of the scattered radiation between RCP and LCP states. Equation (4) describes scattered circularly polarized (SCP) ROA in direct analogy to ICP/ROA. The other two forms of the ROA in Equations (5) and (6) describe the in-phase and out-of-phase forms of dual circularly polarized (DCP) ROA, designated with subscripts \(I\) and \(II\), respectively (i.e. DCP\(_{I}\) and DCP\(_{II}\)).

Another variable of ROA is the scattering angle. All early measurements of ROA were carried out for right-angle scattering. In the 1980s, the advantages of backscattering ROA were realized and, currently, nearly all measurements of ROA are carried out with backscattering geometry, either as unpolarized ICP/ROA, DCP\(_{I}\)/ROA, or unpolarized SCP/ROA.

1.2 Comparison of Vibrational Circular Dichroism and Raman Optical Activity

Both VCD and ROA were discovered in the early 1970s. Each has evolved both experimentally and theoretically to a sophisticated state. Each is very sensitive to the stereostructural features of chiral molecules in solution, and they have similar differences and advantages to their parent spectroscopies IR absorption and Raman scattering. In fact, neither VCD nor ROA can be successfully measured unless an excellent parent IR or Raman spectrum can first be measured. Owing to the more complex nature of carrying out measurements and theoretical analyses, ROA has lagged behind VCD in applications to structural analysis. Further, both the instrumentation for the routine measurement of VCD and software for the ab initio calculation of VCD are now commercially available. Thus, VCD is much more accessible for use by nonspecialists for practical applications, in both academic and industrial settings.

Despite these differences in instrumental and theoretical commercial availability, VCD and ROA are unique complementary forms of VOA, each having its own advantages or disadvantages in particular kinds of applications. The situation is analogous to the complementary nature of IR and Raman spectroscopy in general where differences in sensitivity, solvent interference, and sampling have a role in the selection of the preferred approach. It has been shown that VCD and ROA spectra are strongly noncorrelated in the signs and relative intensities of the bands. The only common element is the structure and vibrational motion of the molecules under study. Thus, adding an ROA spectrum to a study where the VCD spectrum has already been obtained yields new
useful information. Both ROA and VCD have been used for conformational elucidation, optical purity measurements, and the determination of absolute configuration. In both VCD and ROA the abundance of vibrational transitions, each with its own probe of the stereochemistry of the chiral molecule, provides a wealth of structural information.

2 HISTORY AND INSTRUMENTATION

2.1 Vibrational Circular Dichroism Instrumentation

The first measurements of VCD were achieved in the early 1970s with instruments that were relatively crude by today’s standards, but they demonstrated the existence of VCD as a natural phenomenon that could be used to learn about the detailed structure and dynamics of chiral molecules. Later improvements in VCD spectrometers extended the wavelength coverage from the region of hydrogen stretching modes into the mid-IR region where a greater variety of vibrational transitions could be observed. A particularly important advance was the advent of Fourier transform infrared (FTIR) methods for VCD measurement. Virtually all modern VCD spectrometers, including all commercially available models, are now FTIR/VCD spectrometers.

During the 1990s, accessory modules for the measurement of FT/VCD (Fourier transform/vibrational circular dichroism) have been offered by several manufacturers of FTIR spectrometers. In the case of Bomem, Inc., a completely dedicated stand-alone, factory-aligned FT/VCD spectrometers have become commercially available, the ChiralIR®, which has opened the way for widespread applications of VCD spectroscopy not only in academia but also in industry.

The principal applications of VCD spectroscopy include measurements of the conformation, absolute configuration, and enantiomeric excess of chiral molecules. Most of the molecules of interest for study with VCD are biological in origin. Many are molecules of pharmaceutical interest. The most unique application of VCD is its ability to determine absolute configuration in conjunction with ab initio calculations. Remarkably close matches have been achieved between experimental VCD spectra and the corresponding spectra calculated from first principles using quantum mechanical calculations.

2.2 Raman Optical Activity Instrumentation

Early ROA instrumentation was based on scanning dispersive spectrometers. Light levels were low as nonholographic grating technology was used and two or three grating stages were necessary for the reduction of stray Rayleigh radiation. As a consequence, spectra spanning 1000 cm⁻¹ or longer required a day or more to measure. The experimental set-up used in these early measurements was always right-angle depolarized ICP measurements.

Several advances over the years changed this situation dramatically. These included the advent of backsampling geometry, back-thinned charge-coupled detectors, and holographic transmission gratings. Currently, ROA spectra spanning 2000 cm⁻¹ for the most favorable samples can be discerned in less than 10 s. High-quality spectra for these samples can be obtained in approximately 1 min. This advance in speed and sensitivity has opened the way for more sophisticated applications of ROA, such as studying the folding properties of proteins as a function of temperature and other perturbations.

Most recently, attempts are underway to reduce ROA instrumentation to routine operation. These efforts include the introduction of fiber optic coupling to eliminate the effects of beam wander and loss of the precise alignment needed for artifact-free measurements. When this is achieved, ROA is likely to join VCD as a technique available to chemists and biologists wishing to study the conformation of molecules of chemical, biological, and medical interest.

3 INSTRUMENT OPERATION AND PERFORMANCE

3.1 Fourier Transform Vibrational Circular Dichroism Instrumentation and Measurement

3.1.1 Basic Principles

The measurement of a VCD spectrum begins with the measurement of the IR spectrum of a sample. If the IR spectrum cannot be measured with good spectral quality, there is little chance of measuring the corresponding VCD spectrum. The general recommendation is to obtain the IR spectrum with a decadic absorbance in the range 0.1 to 1.0. The expression for the absorbance, \( A(\tilde{v}) \), is given by Equation (7):

\[
A(\tilde{v}) = -\log_{10} \frac{I(\tilde{v})}{I_0(\tilde{v})}
\]

An absorbance of 1.0 corresponds to a percentage transmission value (100 times the ratio in square parentheses) of 10%, whereas an absorbance of 0.1 corresponds to a percentage transmission of about 80%. If the absorbance is greater than 1.0, too little light reaches the detector, whereas if the absorbance is less than 0.1 the sample absorbs too little of the incident IR beam. The optimum value of the absorbance for VCD measurements is approximately 0.4.
In order to measure a good VCD spectrum, it is essential to consider additional issues beyond the quality of the parent IR spectrum. These include the quality of the VCD baseline, the selection of the spectral region, and the setting of the polarization modulator. In addition, for FT/VCD measurements, the appropriate phase correction must be used to obtain the desired spectrum.

### 3.1.2 Instrument Block Diagram

A simple block diagram for the measurement of FT/VCD in the mid-IR region is given in Figure 1. The design corresponds to the so-called double modulation approach to FT/VCD measurement. Here two interferograms are present simultaneously at the detector, one for the ordinary IR spectrum and the other for the VCD spectrum. The method involves measuring each of the interferograms and ratioing the raw VCD spectrum to the raw transmission spectrum of the sample. IR radiation from an interferometer first passes through an optical filter to isolate the spectral region of interest. The beam then goes through a linear polarizer that defines a single state of polarization and then on to a ZnSe photoelastic modulator (PEM) that modulates the polarization between LCP and RCP states at a frequency of 37 kHz. The chiral sample is placed directly after the PEM and the beam is focused with a lens to a HgCdTe detector that is cooled with liquid nitrogen. The detector signal is preamplified and divided into two paths. One is the ordinary IR path that represents the FTIR detector signal is preamplified and divided into two paths. The other is the VCD baseline, the selection of the spectral region, and the setting of the polarization modulator. In addition, other factors beyond the quality of the PEM at a particular wavenumber frequency is given by the first-order Bessel function, $J_1(\sin 2\pi M\tau)$. The final VCD spectrum can be obtained after a VCD calibration spectrum is collected using a multiple waveplate with axes parallel or perpendicular to the stress axis of the PEM followed by a polarizer oriented parallel or perpendicular to the polarization modulator. After this interferogram is digitized, phase corrected, and Fourier transformed, one obtains the instrumental VCD (AC) transmission spectrum (Equation 11),

$$I_{AC}(\tilde{\nu}) = \left[\frac{1}{2}I_{R}(\tilde{\nu}) + I_{L}(\tilde{\nu})\right] \exp(-2\tilde{\nu}V\tau) \sin \alpha_M(\tilde{\nu})$$  \hspace{1cm} (11)

where the retardation angle of the PEM varies sinusoidally at the PEM frequency and is given by Equation (12):

$$\alpha_M(\tilde{\nu}) = \alpha_M^0(\tilde{\nu}) \sin 2\pi M\tau$$  \hspace{1cm} (12)

When the DC and AC transmission spectra in Equations (9) and (11) are ratioed, the result is proportional to the VCD spectrum of the sample, according to Equation (13):

$$\frac{I_{AC}(\tilde{\nu})}{I_{DC}(\tilde{\nu})} = 2J_1(\sin 2\pi M\tau)1.15\Delta A(\tilde{\nu})$$  \hspace{1cm} (13)

Here the efficiency of the PEM at a particular wavenumber frequency is given by the first-order Bessel function, $J_1(\sin 2\pi M\tau)$. The final VCD spectrum can be obtained after a VCD calibration spectrum is collected using a multiple waveplate with axes parallel or perpendicular to the stress axis of the PEM followed by a polarizer oriented parallel or perpendicular to the polarizer in Figure 1. There are four possible settings for the waveplate and polarizer, and the VCD intersection points of the curves they produce define a calibration plot given by Equation (14):

$$\frac{I_{AC}(\tilde{\nu})}{I_{DC}(\tilde{\nu})} = \pm 2J_1(\sin 2\pi M\tau)$$  \hspace{1cm} (14)

Division of this curve into the ratio in Equation (13) isolates the properly calibrated VCD spectrum $\Delta A(\tilde{\nu})$. The phase correction used for the VCD interferogram to eliminate $\theta_{AC}(\tilde{\nu})$ before Fourier transformation is obtained by a special procedure that requires the transfer of the phase correction from a monosignate VCD spectrum to a stressed optical plate. This is necessary.
because the self-phase correction of the VCD spectrum using conventional FTIR software leads to sign errors when the raw VCD spectrum changes sign.

3.2 Examples of Vibrational Circular Dichroism Spectra

The VCD and IR spectra of (s)-(−)-α-pinene between 1350 and 800 cm⁻¹ are presented in Figure 2. The spectrum was measured as a neat liquid with a 73 µm BaF₂ cell and the Chiralir VCD spectrometer. The VCD is half the difference between 20 minute collections of the (−) and (+) enantiomers as discussed further below. Above the VCD spectrum on the same intensity scale is the noise spectrum associated with the VCD spectrum. Note that the VCD spectrum is approximately four orders of magnitude smaller than the corresponding parent absorbance spectrum. Positive VCD bands, according to the definition of ΔA given in Equation (1), absorb LCP radiation more strongly than RCP radiation, and vice versa for negative VCD bands. The VCD spectrum of α-pinene is routinely used as an intensity standard and a basis for comparing the performance of different VCD instruments. This molecule can be sampled in high concentration as a neat liquid and has a rigid stereoconformation due to its fused ring structure. The VCD spectrum of α-pinene is relatively large and not difficult to measure with high signal quality.

A second example of a VCD spectrum is given in Figure 3 where the IR, VCD, and VCD noise spectra of L-valine in H₂O are presented. The spectra were measured on the Chiralir at a concentration of 250 mg mL⁻¹ in aqueous HCl solution using a 12 µm path length cell. This is a more difficult case for two reasons. First, the largest VCD features are 10 times smaller than the largest features for α-pinene and, second, the solvent absorbs some of the IR beam, thus reducing the amount of available IR radiation for measuring the VCD spectrum. Therefore, even though the VCD spectrum for L-valine was collected for 1 h, the signal-to-noise ratio (S/N) is lower than that observed for α-pinene in 20 min of collection. In the following sections we examine in further detail some of the more practical aspects of acquiring final calibrated VCD spectra.

3.3 Baseline Flatness and Stability

Because VCD signals are so small, the instrument baseline at the scale of VCD sensitivity may not correspond to true zero. In Figure 4, the VCD spectra of both enantiomers of α-pinene, and a third spectrum from a solution that is nearly the racemic mixture but still has a few percent of the (−) enantiomer present, are shown. This near racemic spectrum is very nearly the baseline of the empty instrument, and except for a few deviations where the spectrum has large VCD spectral features is identical, to within the noise of the true racemic VCD spectrum. Notice that all three curves pass through the common points where the VCD has a zero value. The baseline shown is relatively flat and close to the true zero of the instrument. Specifying the instrument baseline in the absence of a sample is a criterion for the quality of the VCD instrument. If little care is taken in the choice of optical elements or the alignment of these elements, poor VCD baselines with large deviations from zero on the VCD intensity scale may be encountered. The

![Figure 2](image2.png)  
**Figure 2** Absorbance (bottom), VCD (middle) and VCD noise (top) spectra of (S)-(−)-α-pinene as a neat liquid in a 73-µm BaF₂ cell. Collection time for each enantiomer is 20 min.

![Figure 3](image3.png)  
**Figure 3** Absorbance (bottom), VCD (middle) and VCD noise (top) spectra of L-valine measured in H₂O/HCl solution at a concentration of 250 mg mL⁻¹ and a path length of 12 µm. Collection time for each enantiomer is 1 h.
Figure 4 The VCD spectra of (−)-, (+)-, and (±)-α-pinene, neat liquid, at 73-µm path length, showing opposite VCD for the (+) and (−) enantiomers, and a near racemic mixture exhibiting a slight percentage enantiomeric excess bias toward the (−)-enantiomer.

baseline in Figure 4 corresponds to a very good VCD baseline.

There are two principal sources of baseline deviations in the measurement of a VCD spectrum. One is the empty beam VCD baseline. This is the starting point of all VCD measurements. A second type of baseline deviation, or artifact, varies (in a complex way) with the absorbance of the sample. This second kind of artifact can be isolated, if it is present, by comparing the empty beam VCD spectrum, or the solvent VCD spectrum, with the VCD of the racemic mixture of the chiral sample under investigation. We make this comparison in Figure 5 for valine in H2O, where in this case the empty beam includes the sample cell and H2O solvent. The VCD spectrum of racemic valine should be zero since the sample has no net chirality. Inspection of Figure 5 reveals that the baseline VCD spectrum of the solvent and racemic valine are indeed very close and substantially within the noise level of the VCD measurement. Hence, there is only a baseline deviation of the first kind here, and this is easily removed by subtraction of the solvent VCD. If both kinds of baseline deviation were present, then the correct VCD spectrum could only be obtained by subtraction of the VCD spectrum of the racemic sample or, better still if available, the opposite enantiomer.

Although, it wasn’t stated explicitly earlier, opposite enantiomers have opposite VCD spectra with respect to the baseline for the sample. This is illustrated in Figure 6 for L-valine and D-valine. The final spectrum in Figure 3 was obtained by subtracting the VCD spectrum of D-valine from that of L-valine and dividing by two. This subtraction removes all sources of artifacts. In many cases, however, both enantiomers are not available. For such cases, it is important that the VCD instrument is not sensitive to absorption artifacts, and ideally that the empty instrument or solvent artifacts are as small as possible.

It has been observed that absorption artifacts increase in importance (and annoyance) as the empty instrument baseline deviates more significantly from true zero.

The reliable subtraction of VCD spectra obtained from successive measurements, requires good instrument stability over the time of both measurements. Stability can be checked by running a series of VCD spectra to look for variations or baseline wander outside the expected...
noise level. This can be checked in several ways. One is to determine a noise curve for each VCD measurement that is the result of dividing the VCD collection into two successive blocks. Adding these blocks yields the final VCD spectrum and subtracting removes all the VCD features but leaves only the effects of noise and baseline instability. Examples of such noise curves are presented in Figures 2 and 3. From these the noise level across the spectrum is more apparent than it is in the spectrum itself, and second, the flatness and position of the noise curve at the zero level attests to the stability of the two measurements.

Another approach to testing VCD instrument stability is presented in Figure 7 where the results of 12 successive 20-min measurements of \((−)-\alpha\)-pinene are presented. The spectra were measured over a 4-h period without any interruptions or sample changes. A high level of reproducibility is observed with no systematic drift outside the noise level of the measurements. Below approximately 850 cm\(^{-1}\) the noise level increases owing to absorption in the beam from BaF\(_2\) windows in the sample cell.

3.4 Intensity Calibration and Reproducibility

As mentioned above, Equation (14) describes a calibration curve obtained from the nonzero intersection points of a pair of VCD calibration curves. These intersection points and the resulting calibration represent unit VCD intensity at each wavenumber frequency. In Figure 8 the two curves are shown with their connected intersection points. The resulting calibration curve is shown for a setting of the PEM with maximum VCD efficiency near 1100 cm\(^{-1}\). For the region near this frequency the calibration curve is nearly the same value. The decrease in VCD efficiency toward higher frequencies is the result of lower values of the Bessel function and the exponential lock-in decay factor which disadvantages higher frequencies.

Presently, work is in progress to define an absolute intensity standard for VCD based on the spectrum of \((−)-\alpha\)-pinene. Spectra for this sample and one other have been obtained from a number of laboratories where VCD instruments are located. To illustrate the level of agreement obtained for two such instruments, Figure 9 shows VCD spectra of \((−)-\alpha\)-pinene from two laboratories, the laboratory of Philip Stephens at the University of Southern California using the Chiralir\textsuperscript{TM} (solid line) and the laboratory of one of the co-authors at Syracuse University using a homebuilt instrument based on Nicolet 850 spectrometer (dashed line). Both VCD spectra are presented in terms of the absorption coefficient, \(\Delta \varepsilon\), to eliminate the effects of differing path length, and hence different \(\Delta \varepsilon\) absorbance values, for the
two measurements. These two VCD measurements from instruments of different design are in relatively close agreement. Differences that do exist arise from variations in the way the calibration measurement was executed and possible errors in the path lengths of the cells used. It is expected that with sufficient care, agreement for the absolute intensity values of the \((-\alpha\)-pinene VCD spectrum in the mid-IR region can be determined to within a few percent. Once this has been accomplished, a new way to calibrate VCD, namely relative to the \((-\alpha\)-pinene spectrum, can be established.

### 3.5 Signal-to-noise Ratio

An important variable in the measurement of VCD spectra is the S/N. All VCD spectra, no matter how large, take longer to acquire than the corresponding FTIR absorbance spectra. The disadvantage of four orders of magnitude is overcome in part owing to the sophisticated electronic pathway that permits isolation and amplification of the VCD signal independently of processing the ordinary IR spectrum. The VCD spectra are generally too small to obtain by simply obtaining the absorbance spectra of LCP and RCP separately and subtracting.

To obtain a VCD spectrum at the desired S/N, one needs to decide how long to collect the spectrum. Figure 10 shows the VCD and noise spectra for a single enantiomer, with no baseline correction, of \((-\alpha\)-pinene after 1 min of collection, 5 min of collection, and 20 min of collection. Dramatic increases in the S/N can be seen. The general rule of signal averaging for FTIR and FT/VCD is that the S/N improves as the square root of the increase in time of collection. Thus the 5 min scan has lower noise than the 1 min scan by a factor of \(1/\sqrt{5}\), and the improvement gained in collecting for 20 min instead of 5 is a factor of 2. For long scans it advisable to collect the spectra in blocks, say 1 h each, so that if the liquid nitrogen runs out, the sample degrades, or some undesired change in the measurement occurs, the prior blocks of data will be available and safe.

### 4 BIOLOGICAL EXAMPLES

Naturally occurring biological molecules of all varieties can be measured by VCD. These include amino acids, as illustrated above in the case of L-valine, peptides, proteins, nucleic acids, and sugars. This section provides further examples of biological molecules of several classes. An important issue to resolve for the sampling of any biological sample is the solvent. Water (H\(_2\)O or D\(_2\)O) is an important solvent for biological samples. All but a few solvents have regions of intense absorption in particular regions of the mid-IR. A useful preliminary exercise when considering a solvent is to measure the transmission spectrum of the pure solvent near the path length of interest for the sample measurements. In Figure 11 the transmission spectra for H\(_2\)O and D\(_2\)O are presented where, for the sake of direct comparison, a path length of 12 \(\mu\)m is used for both solvents. In practice, shorter path lengths are generally used for H\(_2\)O and longer ones for D\(_2\)O.

#### 4.1 Proteins

Proteins exhibit strong VCD in the amide I and II regions of the IR spectrum, and the chirality of the constituent amino acids drives the overall sense of the helical structure.\(^{20,21}\) In Figure 12 four examples of protein VCD are shown. In Figure 12(a) and 12(b) the VCD

VIBRATIONAL OPTICAL ACTIVITY OF PHARMACEUTICALS AND BIOMOLECULES

Figure 12 Absorbance and VCD spectra in the amide I and II regions for two proteins: (a) hemoglobin in H₂O, (b) chymotrypsin in H₂O, (c) hemoglobin in D₂O, and (d) chymotrypsin in D₂O. Spectra in H₂O were measured at a concentration of 150–200 mg mL⁻¹ and path lengths of 4–6 µm and spectra in D₂O were measured at a concentration of 20 mg mL⁻¹ and 80-µm path lengths.

and IR spectra for hemoglobin and α-chymotrypsin in H₂O, respectively, are presented, and the corresponding spectra in D₂O are given in Figure 12(c) and 12(d). The measurements were made with the Chiralir

The absorbance spectra in all cases are corrected for solvent absorption, and the two prominent bands, near 1650 cm⁻¹ and 1530 cm⁻¹ are the amide I and II bands, respectively. In D₂O, small changes occur in the amide I region and the amide II band shifts to lower frequency, near 1450 cm⁻¹, although some unexchanged amide groups still remain. The secondary structure of hemoglobin under these conditions is predominantly α-helix, whereas the structure of α-chymotrypsin is primarily β-sheet. Both the VCD and IR spectra provided here
are typical for proteins with this secondary structure, and the distinct differences in these two cases reflect the sensitivity of VCD to the conformation of protein structure.

4.2 Nucleic Acids

Nucleic acids are chiral by virtue of the sugar–phosphate backbone which in turn drives the helical structure of the entire molecule. The VCD technique is sensitive to all regions of nucleic acids, and in particular to the base stacking regions between 1750 and 1550 cm\(^{-1}\). In Figure 13, the VCD and IR spectra of salmon sperm DNA dissolved in D\(_2\)O is presented. Under these conditions, the DNA helix is in the B-form conformation. The measurements were made with the Chiralir\textsuperscript{™} at a spectral collection time of 2 h at a resolution of 8 cm\(^{-1}\). The concentration of DNA was 15 mg mL\(^{-1}\) and the path length was 75 µm. The VCD and IR spectra were corrected by subtraction of the corresponding background D\(_2\)O spectrum.

Figure 13 Absorbance and VCD spectra of salmon sperm DNA in D\(_2\)O solution at a concentration of 15 mg mL\(^{-1}\), 75 µm path length, 2-h collection time.

4.3 Sugars

Sugars have multiple centers of chirality and exhibit strong VCD spectra. Their conformation is easily studied in a variety of solvents. In Figure 14, the VCD and IR spectra of \(\alpha\)-D-glucose in dimethylsulfoxide-d\(_6\) (DMSO-d\(_6\)) is presented.\textsuperscript{23} The solvent VCD and IR background spectrum were subtracted to obtain the result presented. The lower spectral limit is 1100 cm\(^{-1}\) because the solvent absorbs strongly below that point. The concentration used was 0.5 M or 90 mg mL\(^{-1}\) and the path length was 70 µm.

Figure 14 Absorbance and VCD spectra of \(\alpha\)-D-glucose in DMSO-d\(_6\) solution at a concentration of 90 mg mL\(^{-1}\) and a path length of 70 µm.

Figure 15 shows the VCD and IR spectra of ibuprofen, a common analgesic molecule. The VCD and IR spectra of ibuprofen are presented in Figure 15 in the region between 1600 and 800 cm\(^{-1}\). The spectrum was obtained using a 75-µm cell at 4 cm\(^{-1}\) resolution on the Chiralir\textsuperscript{™}. The collection time was 1 h per enantiomer where the final spectrum is half the subtraction of the two enantiomers. Ibuprofen was sampled as a solution in CDCl\(_3\) at a concentration of 250 mg mL\(^{-1}\). The absorbance spectrum was corrected for solvent absorption.

As a second example, the VCD and IR spectra of warfarin in CDCl\(_3\) are presented in Figure 16. The spectra

5 PHARMACEUTICAL EXAMPLES

Increasingly the development of chirally pure pharmaceutical molecules is gaining importance. These molecules offer a rich variety of structural motifs for intended purposes in many different areas of application. In this section, two examples of chiral pharmaceutical molecules are provided as examples of the structure complexity in this class of molecules. The VCD and IR spectra are equally varied and offer the prospect of studying and specifying the stereochemistry of these interesting molecules.\textsuperscript{24}

Ibuprofen is a common over-the-counter analgesic molecule. The VCD and IR spectra of \((R)\)-(−)-ibuprofen are presented in Figure 15 in the region between 1600 and 800 cm\(^{-1}\). The spectrum was obtained using a 75-µm cell at 4 cm\(^{-1}\) resolution on the Chiralir\textsuperscript{™}. The collection time was 1 h per enantiomer where the final spectrum is half the subtraction of the two enantiomers. Ibuprofen was sampled as a solution in CDCl\(_3\) at a concentration of 250 mg mL\(^{-1}\). The absorbance spectrum was corrected for solvent absorption.

As a second example, the VCD and IR spectra of \((R)\)-warfarin in CDCl\(_3\) are presented in Figure 16. The spectra
were measured on the Chiralir™ at 4 cm⁻¹ resolution as a single enantiomer in a 3 h collection period. The concentration of the sample was 8.6 mg mL⁻¹ at a path length of 500 μm. The VCD intensity in this spectrum is approximately 10 times smaller than that of α-pinene as can be discerned from the VCD intensity scale for similar IR absorbance intensities. This demonstrates that molecules with relatively small VCD can still be measured with good signal quality. Note the richness of the vibrational band structure for this molecule across a wide range of frequencies.

6 AREAS OF APPLICATION

VCD, and ROA, can be used for a wide variety of stereostructural analyses. The applications of VCD fall into three areas. The first is conformational analysis, and we have seen in the previous figures examples of VCD spectra where the principal objective in obtaining the spectra has been to study the solution conformations of the selected biological molecules. This is the oldest and most basic use of VCD spectra. Since the mid 1970s, VCD has been used as a research tool in academia to study the conformational properties of molecules where the absolute configurations were well known and the optical purity was assumed to be as high as possible, typically near 100%.

The other two areas of application of VCD are more practical and have come to the fore with the increasing interest by the chemical and pharmaceutical industries in the potential of VCD for determining the optical purity of manufactured samples and the absolute configuration of new chiral molecules intended for medicinal application. This section provides examples of the use of VCD in these two areas.

6.1 Enantiomeric Excess

Prior to VCD there were primarily three techniques used for the determination of enantiomeric excess. The oldest method is the measurement of optical rotation. If the rotational angle for the pure compound is known, measurement of the optical rotation provides a measure of optical purity. The principal shortcomings of this method are that, first, only one spectral datum is associated with the measurement and, second, the value is very sensitive to the density of the sample and hence its temperature. Optical rotation has been replaced over the years by two new techniques. One is NMR shift reagent measurements and the other is chiral chromatography. In the NMR method, a chiral NMR shift reagent is added to the sample as a perturbant. Opposite enantiomers in the sample will experience shifts in some of their NMR resonances in opposite directions, and the areas of these shifted bands can be compared to determine the relative percentages of the two enantiomers. The drawbacks here involve finding suitable shift reagents, and difficulties arising when multiple chiral centers are present. In addition, the sample is altered in the process of measurement. In chiral chromatography a physical separation of the two enantiomers is effected by a chiral substrate in a column. If
The VCD spectra of L-valine in H$_2$O/HCl under conditions of Figure 3 for single enantiomer at percentage ee values of 100, 90, 80, 60, 40, and 20% ee. The VCD data were fitted to these known values using partial least squares (PLS) analysis and the optimized values obtained for these samples, as determined by VCD, were 100.5, 88.5, 75.5, 59.6, 44.3, 18.5% ee. The error range for these six determinations is 0.4–4.3% and the standard error (the square root of a result of 5 divided into the sum of the squares of the errors) is 2.26%. Unknown errors may also be present in preparation of samples, although they are presumed to be smaller than VCD spectral determination of percentage ee. Samples with higher intrinsic noise levels have produced errors as low as 0.4% ee, but the case here may be a more typical result. Thus VCD is available as a straightforward method with which to reliably determine percentage ee under a variety of nonperturbing sampling conditions. If only a qualitative monitor of the percentage ee, say to within 2% ee, and the sample integrity were desired, results could be available off-line on a 10–20 min cycle time or less depending on the S/N of the VCD measurement.

### 6.2 Absolute Configuration

Presently, there is only one conventional spectroscopic method for the determination of the absolute configuration of an unknown chiral molecule without reference to a prior structure or correlation. That is single-crystal X-ray diffraction. For this method the molecule of interest must form a pure single crystal of sufficient size for the X-ray analysis. In most cases use of a heavy atom crystal dopant is necessary to establish the absolute phase, and hence the absolute stereochemistry.

VCD now offers a viable alternative to X-ray analysis. As VCD spectra are usually measured in the solution phase, it is not necessary to grow a crystal or dope the crystal for analysis. The absolute stereochemistry is established by comparing the solution-phase VCD spectrum to the results of an ab initio quantum chemistry calculation. The absolute configuration used for the calculation is known. If the measured VCD agrees with the theoretical spectrum, the absolute configuration of the sample molecule is the same as that calculated, and if the experimental signs are opposite to the corresponding theoretical ones, so then is the absolute configuration of the sample molecule. In addition to this definitive method of determination of absolute configuration without reference to a standard compound, VCD can be used empirically to show the stereochemical relationship between two closely related molecules.

In principle, electronic CD could also be used in the same way for absolute configuration determination; however, there are several difficulties. First, there are usually only a few bands rather that a dozen or so for points of comparison. Second, calculating the electronic CD spectrum requires good quantum mechanical descriptions of both the ground and the excited electronic states.
whereas only the former is needed for VCD calculations; VCD arises from only the vibrational modulation of the ground electronic state and is not a two-electronic-state phenomenon. It is well known that excited electronic states are much more difficult to calculate than the corresponding ground electronic state. Finally, not all molecules have electronic states in the accessible region of the electronic spectrum, as is the case below.

In Figure 18, the calculated and observed VCD and IR spectra for (S)-(−)-trans-pinane is shown. The absolute stereochemistry of this molecule is a pure hydrocarbon and has no functional groups. Hence its electronic CD spectrum would be difficult, if not impossible, to measure with a conventional electronic CD instrument. Inspection of the figure reveals a high level of agreement, both in signs, relative magnitudes, and absolute magnitudes of all the bands. No adjustable parameters were invoked in the calculation, only a choice of bandwidth for the theoretical intensities. The experimental spectrum was obtained with the Chiralir™ from Bomem/BioTools and ab initio molecular orbital software for VCD intensity calculation in Gaussian 98 from Gaussian Inc. have hastened the advance of VCD for widespread application beyond the laboratories of the VCD specialists. Similar advances will eventually be made for ROA, and then both approaches to VOA will be available for broad use in the study of chiral molecules.

7 CONCLUSIONS

VOA, consisting of IR/VCD and vibrational ROA, has evolved to a point of routine stereochemical application. This article has introduced the basic principles of these two closely related techniques and has illustrated the principal areas of application of VCD, namely conformational analysis, optical purity measurement, and absolute configuration determination. The availability of commercial instrumentation for VCD such as the Chiralir™ from Bomem/BioTools and ab initio molecular orbital software for VCD intensity calculation in Gaussian 98 have hastened the advance of VCD for widespread application beyond the laboratories of the VCD specialists. Similar advances will eventually be made for ROA, and then both approaches to VOA will be available for broad use in the study of chiral molecules.

The mammalian brain is the most complex structure known to science. Our behavior, feelings, thoughts, and maybe even consciousness itself, may be a reflection of the interplay of electrical and chemical signaling that create these states, and how the physical brain gives rise to the properties of mind remains a major unanswered question. It is clear, however, that many of the drugs used empirically in the treatment of neurological disorders, such as Parkinson’s disease, schizophrenia and depression, as well as mind-altering substances of abuse, have specific chemical actions on nerve cells in the brain, highlighting the importance of chemical signaling in the functioning of neural networks.

A growing number of methodologies are being developed, including sampling, spectroscopic and electrochemical, to study neurochemical phenomena in the living brain. One such set of techniques focuses on the detection of substances released from nerve cells, using amperometric electrodes and voltammetry in vivo (VIV) techniques. By implanting a microvoltametric electrode in a specific brain region, applying a suitable potential profile and recording the resulting faradaic current, changes in the concentration of a variety of substances in the extracellular fluid (ECF) can be monitored with sub-second time resolution over extended periods. This allows investigations of the functions and roles of specific neurochemicals in neuronal signaling, drug actions, and well-defined behaviors. The main limitations associated with VIV is, on the one hand, the limited number of ECF species that are electroactive, and on the other, the fact that electroactive substances present tend to oxidize at similar potentials, interfering with each other’s detection. These restrictions are being overcome by ongoing developments, including the design of biosensors to broaden the range of target analytes and permselective membranes to block interference.
1 INTRODUCTION

1.1 Intact Brain Preparation

Mammalian behavior is a reflection of the activity of the central nervous system (CNS), and in particular the brain. The brain is adept in a wide range of functions, including: sensory input and processing; behavioral output or response; subtle colorings of the animal with feelings such as depression, anxiety and reward; memory; and in higher animals it is involved in phenomena such as language and imaginative thought.\(^1\)

The substrates of these diverse functions are complex networks of complex units – nerve cells or neurons. Each neuron consists essentially of a cell body from which extend a large number of cytoplasmic projections. One of these projections, the axon, is usually much longer than the others, and may bifurcate several times; the remaining, smaller, extensions are the dendrites. The ends of the axon (nerve terminals) are normally swollen and contain specialized organelles for storing chemical messengers. Most neurons are electrically isolated from each other, and form networks by interfacing through anatomically well-defined gaps (synapses), usually between the terminal of one neuron and the cell body or dendrites of another (Figure 1).

Although the processing of electrical signals may be considered the primary function of nerve cells in the brain,\(^2\) intercellular chemical signaling plays a major role in determining the properties of neural networks. The individual nerve cells normally communicate their state of excitation or inhibition to other neurons by releasing chemical messengers across their synapses, and the CNS uses a wide variety of intercellular chemical messengers (neuromediators) in synaptic signaling. (The term neuromediator is used here to include classical neurotransmitters, neuromodulators and neurohormones.) In addition, each released neuromediator substance can bind to a range of different receptor proteins embedded in the membrane of the target cell. Some receptors (ionotropic), when activated, open ion channels that lead to millisecond changes in the electrical potential across the membrane. Others (metabotropic) are linked to enzymes located on the intracellular side of the membrane; when activated these receptors can either accelerate or inhibit the production of intracellular ‘second messenger’ systems that can change the condition of the target neuron over extended periods of time. This combination of diverse neuromediators, receptors and mechanisms of interaction are some of the factors that enable the CNS to function over a vast spectrum of timescales, producing responses ranging from reflex actions to memories lasting many decades.

Figure 1 shows a schematic representation of intercellular chemical signaling at a synapse between a nerve terminal and target neuron. In the resting state, the nerve cell membrane (lipid bilayer containing a variety of attached and transmembrane proteins) is polarized at about \(-70\text{ mV}\) (negative on the inside) due to a transmembrane concentration gradient of \(K^+\) (high inside) and the presence of \(K^+\)-selective

![Figure 1](image-url)
ion channels that are permanently open (leakage channels).

A precursor, such as an amino acid, is taken from the ECF into the terminal where one or a number of enzymes transform it into the neuromediator substance characteristic of the particular neuronal pathway. Although most of the newly synthesized neuromediator is taken up into storage vesicles, some will be inactivated before reaching the vesicles by metabolic enzymes present in the terminal. When an action potential (rapid depolarization, followed by repolarization of the membrane potential; total duration about 5 ms) propagates down an axon to the nerve terminal, voltage-sensitive Na⁺ ion channels open, causing depolarization of the terminal membrane and the opening of voltage-sensitive Ca²⁺ channels, the influx of Ca²⁺, and ultimately to the fusion of vesicles that release their neuromediator content into the synapse; a few milliseconds later, the opening of voltage-sensitive K⁺ channels results in repolarization. This Ca²⁺-dependent exocytotic release of neuromediator is surprisingly fast, occurring within microseconds of the start of the action potential in the terminal. (3)

Once in the synapse, the neuromediator molecules may bind to a range of different receptor proteins on either the presynaptic or postsynaptic membrane. On the presynaptic side, receptors may be linked to a ‘second messenger’ enzyme involved in the synthesis of neuromediator (negative feedback control). Postsynaptically, receptors may also be linked to a second messenger system or to ion channels for Na⁺, K⁺, Ca²⁺ or Cl⁻ that control the membrane potential of the target neuron. Inactivation of the chemical signal is achieved either by re-uptake of neuromediator into the terminal (and other sites, such as glial cells) through specific ion-coupled carrier uptake sites (also capable of releasing cytoplasmic neuromediator by a Ca²⁺-independent mechanism) and subsequently metabolized, or may be metabolized extracellularly. The metabolites can diffuse into the ECF that also contains small concentrations of neuromediator that overflow from the synapse. The concentrations of metabolites and neuromediator in the ECF can also be regulated by the rate of their excretion into the cerebrospinal fluid or across the blood–brain barrier (BBB).

One of the key elements in understanding the role of each neuromediator substance in neural networks is a knowledge of release rate, and Adams et al. (4) suggested that voltammetric electrodes implanted directly in the intact brain might be used to monitor electroactive neuromediators in the CNS (see section 2). However, electrodes generally employed for neurochemical analysis using VIV are ~5–300 µm in diameter and monitor an average concentration of analyte in the medium surrounding cells, the ECF, and not directly in synapses that are orders of magnitude smaller (typically 20–30 nm from terminal to target, see Figure 1). It is not clear at present what the relationship is between release of different neuromediators into the synapse and resulting ECF levels, although balance between release and re-uptake (Figure 1) is involved. It is also debatable whether neuromediators released into a synapse have additional extrasynaptic functions, so that the synapse might be designed to ‘leak’. For example, extrasynaptic receptors have been reported for the main excitatory CNS neuromediator, glutamate, (5) as well as evidence for the diffusion of neuromediators, such as glutamate, outside the synaptic cleft. (6) An additional factor is that some neuromediators, such as norepinephrine (NE), are not released into anatomically well-defined synapses, but from simple swellings along the axon, so that their sphere of influence may extend far (up to 100 µm) (7) into the ECF.

Neuromediators and their metabolites in the ECF have been studied using VIV and a variety of perturbations that fall into two main categories (see Figure 1): those that cause depolarization of the terminal, including electrical stimulation, application of extracellular K⁺, administration of agents that bind to receptors linked to ligand-gated Na⁺ channels (e.g. glutamate), and behavioral activation (e.g. tail pinch); and those that cause changes in ECF levels by mechanisms not involving depolarization directly, such as inhibition of synthesis (e.g. α-methyl-p-tyrosine), displacing neuromediators from the terminal (e.g. amphetamine), inhibition of metabolic enzymes (e.g. pargyline), or blocking re-uptake (e.g. cocaine). A number of reviews on the principles and applications of voltammetric analysis of the ECF have been published, and a representative selection is cited here. (8–22) Original forms of some of the concepts presented in this article can be found in previous reviews. (13,19,21)

1.2 Other Brain Preparations

As a complementary approach to voltammetric recording in the living brain, the brain slice preparation has proved useful for studying the properties of individual neural pathways using voltammetric techniques. (15,20,22–25) A slice of brain containing the projection of interest (often the dopaminergic nigrostriatal system) is maintained in a physiological medium in vitro. This allows direct manipulation of the pathway with, for example, electrical or chemical stimulation, and the application of drugs affecting release, such as neuromediator synthesis inhibitors and receptor ligands (Figure 1), with reproducible results reported for up to 9 h. (26) Details of this preparation are given in article: Neurotransmitters, Electrochemical Detection of.
Pioneered by Schenk et al., another preparation of brain tissue, that has been used in voltammetric studies in vitro, is obtained by dissecting a particular brain region (usually the striatum) followed by its disruption, using a rotating disk electrode (RDE), to produce a suspension of whole tissue. With the RDE held at a constant potential to detect neuromediators, analogs or other agents added to either this suspension or the more classical synaptosomal preparation of striatal tissue, the mechanism of DA uptake, \( \text{DA} \) ligand structure/activity relationships and interactions with drugs of abuse have been studied.

Understanding the functioning of brain neurons can also be advanced by studying the properties of other cell types and peripheral neurons isolated in vitro. Investigations of the chemistry within the cytoplasm of individual cells in vitro are now possible using submicron carbon ring, carbon fiber or Pt electrodes, and intracellular \( \text{Ni}^{2+} \); oxygen; \( \text{DA} \) and serotonin have been monitored electrochemically. The majority of voltammetric reports on the behavior of isolated cells, however, have concentrated on the mechanism of release of catecholamines from adrenal medullary chromaffin cells and serotonin from mast cells, and signals associated with the release of neuromediator from single vesicles have been described. Recent work on the release of peptide hormones from single cells has also been reported.

1.3 Legal and Ethical Considerations

Legislation controlling the use of animals in scientific experiments varies from country to country, with some countries having strict legal requirements and others having poor, or in some cases no, legislation. For example, in the United Kingdom, legislation is enforced by the Home Office and is covered by the Animals (Scientific Procedures) Act 1986. The latter operates on a dual licence system: a personal licence for individual workers, specifying procedures and types of animals that may be used according to competence, training, qualifications and experience; and a project licence covering each specific programme of work. In the United States, the system is generally based on institutional licences being required for all projects and procedures. Large funding agencies for biomedical research, such as The Wellcome Trust (UK) and the National Institutes of Health (USA), also have very specific regulations concerning the welfare of animals and proper codes of practice. In addition to national legislation and institutional requirements, there are also international laws, such as European Directive 86/609/EEC, relating to the protection of animals used for experimental and other scientific purposes. Generally, all such policies are designed to control procedures that may cause pain, suffering, distress or lasting harm to animals used in scientific procedures. Provisions generally cover several areas, including a specification of the programme of work, the purpose and scientific justification for the work, a full description of the procedures involved (experimental protocol), the types of animals to be used, and an assessment of the potential severity of each procedure and the scientific programme as a whole.

The ethics of using animals in scientific experiments has become a very important issue. All use of animals in research for human benefit creates a dilemma; the justification for using the animal depends on it being different from the human, while the validity of the results obtained depends on the similarity of the animals, and their responses, to those of the human. Important considerations are:

- Can one justify what one is doing and does the potential benefit derived from the results outweigh the value of the animal? Potential benefit must be weighed against any pain, suffering (e.g. isolation or confinement) or lasting harm that may be caused to the animals used.
- Is it possible to achieve the same benefit by either carrying out an in vitro experiment, using a mathematical model, or using a different animal species lower in the phylogenetic scale?
- Can one use fewer animals by better experimental design, or by collaborating with colleagues so that as many tissues as possible from each animal are utilized?
- Can one alter the experimental method in some way to decrease the animal’s potential suffering, for example, by an alteration in surgical technique, improvements in housing or bedding or by altering the drug dosage regime for a reduced volume or reduced frequency?

The last three considerations are often referred to as ‘the three Rs’ (replacement, reduction, and refinement) and form the backbone of any ethical review of animal research. Since this section is intended only to provide general guidelines relating to legislation and the ethics of using animals, the reader is urged to consult and examine texts for a more detailed consideration of the law and the ethics of animal use before embarking on such research.

2 HISTORY

Although reports of voltammetry in the living brain go back at least as far as 1958 when Leland C. Clark demonstrated the feasibility of voltammetric recording in brain tissue in vivo for oxygen and ascorbic acid (AA)
The concept of applying voltammetric techniques to monitor changes in the concentration of electroactive neuromediators in brain ECF is generally attributed to Ralph N. Adams et al.\(^{[4]}\) The paper describes attempts to detect neuromediator DA in anesthetized rat brain, using a carbon paste electrode (CPE) and cyclic voltammetry (CV). Even at this early stage, the authors successfully identified many of the problems and factors affecting the shape of voltammograms recorded in brain tissue. Thus, reference is made to depletion of the ECF around the electrode by the scan leading to thin-layer behavior, tortuous diffusion in the tissue, heterogeneous distribution of target analytes in various compartments in the brain, overlap of different signals, and perturbation of the tissue by the implanted electrodes. Quite inspirationally, the authors also suggested a number of strategies to address some of these problems, such as the use of permselective membranes and immobilized enzymes, tactics that proved successful many years later.

### 2.1 Original Interference Problem

Despite the aim to detect neuromediator DA in this first study using VIV, Adams et al.\(^{[4]}\) concluded correctly that the voltammograms recorded were due to a number of different compounds present in the ECF, oxidizing at similar potentials at the CPE, and that AA, not DA, was the principal contributor. The initial success, however, was soon undermined by a widespread assumption that the concentration of AA in brain ECF was essentially constant. This led to conclusions that changes observed in the voltammetric signal were due to other species such as DA and serotonin. It was not until the early 1980s that this assumption had to be abandoned when two independent studies\(^{[61,62]}\) showed that systemic administration of a commonly used DA-releasing drug, amphetamine, also caused changes in the concentration of AA in brain ECF.

Having established that ECF brain AA concentrations respond to a wide variety of stimuli, including pharmacological, electrical and behavioral (see section 7.3 and review by O’Neill\(^{[63]}\) for details), efforts began in earnest to resolve the different contributions present in brain voltammograms. Two basic approaches have been used: eliminating undesired signals (e.g. those of AA and neuromediator metabolites), principally by means of chemical modification of the electrode surface; and separating the voltammogram components into identifiable signals using a combination of surface modification, applied potential waveforms, and mathematical analysis of the current; examples of validation of specific sensors are described in section 4. These developments in VIV over the past two decades have led to its establishment as a valuable tool in many aspects of neuroscience research, including anatomical, pharmacological and behavioral studies.\(^{[6–22]}\)

### 2.2 Analytical Problems of Voltammetry In Vivo

It should be stressed that the application of VIV involves far more than a straightforward transfer of expertise gained from the practice of voltammetry in vitro. In addition to being anatomically complicated and containing a wide range of electroactive substances, brain tissue presents a complex chemical environment that includes surfactants (lipids), electrodes poisons (proteins), electrocatalysts such as glutathione and AA, and a tissue matrix that both restricts mass transport to the electrode surface and reacts physiologically to the presence of the probe.\(^{[64]}\) Thus, the behavior of a particular electrode and voltammetric technique in vitro might well be different to its behavior in vivo, because both modification of the electrode surface by components of the tissue,\(^{[65]}\) and the differences in mass transport,\(^{[66–69]}\) could lead to different responses (sensitivity, selectivity, stability, etc.) in the two environments.\(^{[70]}\) Therefore, detailed characterization in vitro of parameters such as detection limits is of little use, and may be misleading in an application like VIV where the major issue is that of selectivity rather than sensitivity.

Indeed, the complexity of the system is such that some forms of VIV may have been characterized in error in the literature, and subtle differences in methodologies might lead to an inability to reproduce reported characteristics. It is advisable, therefore, that each laboratory

considering adopting VIV, having decided on the form that promises to be suitable for the neurochemical study in question, should either characterize the technique in detail in vivo or, at least, test it with a series of well-documented pharmacological challenges. For example, a sensor designed to detect striatal DA must be relatively unresponsive to other ECF species, especially AA and catechol metabolites (see Table 1). The first selectivity test should be against AA, because of its several thousand-fold excess over DA in brain ECF. This selectivity can be ascertained by, for example, systemic administration of a DA-receptor agonist, such as apomorphine, that causes decreases in striatal ECF DA levels while increasing those of striatal AA. If the sensor passes this test, then systemic administration of a MAO inhibitor (see Figure 1 legend), such as pargyline or amphetamine, can be used to test selectivity for DA versus catechol metabolites by increasing the concentration of DA in the ECF and decreasing catechol metabolite levels. Note, however, that this second test can only be interpreted correctly if the sensor has passed the first selectivity test, because drugs like pargyline and amphetamine also cause increases in striatal AA concentration in the ECF.

The route of drug administration in these tests is also important. Particularly, systemic injection of drugs (intraperitoneally, subcutaneously, etc.) can have very different effects compared with their local perfusion directly into the brain. An additional precaution is that of timescale. A technique demonstrated to detect DA selectively on a fast timescale (seconds) cannot be assumed to do so on slower timescales (minutes) because changes in neuromediator concentrations tend to be much faster than those of their metabolites. These points will be developed below.

3 SUBSTANCES TARGETED WITH VOLTAMMETRY IN VIVO

One of the main problems associated with producing identifiable voltammetric signals directly in vivo is that the ECF contains a wide variety of electroactive species that oxidize at similar potentials on many electrode materials. Moreover, baseline ECF concentrations of the main target molecules – neuromediators – are orders of magnitude lower (often nanomolar) than those of other endogenous electroactive species (see Table 1). Factors affecting determination of ECF concentrations are discussed elsewhere.

Electroactive compounds in the ECF include: small, highly permeable, species such as dioxygen and NO; AA, that has a range of general antioxidant and specific neurochemical functions; neuromediator catecholamines such as DA and NE, as well as their metabolites DOPAC, 3MT and HVA; the 5-hydroxyindole neuromediator, 5HT, (serotonin) and its metabolite 5HIAA; amino acids and the purine metabolite UA. Electroinactive or badly behaved electroactive species, such as glutamate, glucose and lactate, can now be targeted in vivo using biosensors, especially enzyme-modified electrodes.

The range of oxidation potentials for ECF analytes (against SCE) and estimated baseline extracellular concentrations are given in Table 1. In general, the higher the potential needed to detect the analyte of interest, the greater the risk of interference, so that at the potential needed to detect NO, say, interference by amino acids such as tyrosine and tryptophan, and molecules containing these moieties, needs to be considered. One feature that has helped separate voltammetric signals for AA and neuromediator metabolites from those of the neuromediators themselves is their ionic form at physiological pH. Because the former are anionic and the latter cationic at pH 7.4, modification of the electrode surface by anion repelling agents can increase the selectivity of the sensors for the parent neuromediator. The problems of VIV signal resolution have also been tackled with some success by choice of working electrode material, fine-tuning the shape of the applied potential, modification of the surface properties of the working electrode, and mathematical treatment of the recorded current.

4 ELECTRODE TYPES AND PREPARATION

4.1 Auxiliary and Reference Electrodes

A wide variety of auxiliary and reference electrodes have been used for VIV. The main criterion is that the electrodes are small to minimize tissue damage upon implantation into the tissue, the most common placement site. Minimal disruption can also be achieved by locating these electrodes between the brain and skull (see section 6), although care is needed to ensure that these stay connected to a conducting medium. Using metal items already in place for other functions, such as a stainless steel guide cannula as the auxiliary electrode, will also reduce damage. Recordings made in a metal frame or cage do not normally require explicit earthing of the animal, although this may be needed for recordings where plastic containers are used.

The reference electrode needs to be chosen with greater care because of the need for chemical reversibility at its surface. A common form is AgCl-coated Ag wire housed in a pulled micropipette containing a gelatinous solution of NaCl. This has the advantage that very small tip sizes are achievable, but disadvantages include the formation of bubbles in the tip and gradual leaching of the NaCl over extended periods in the tissue. In part to overcome these...
two problems, the implantation of AgCl-coated Ag wire directly into the tissue is quite common. The consequent problem here appears to be the dissolution of the AgCl in the tissue, although a Nafton®-coating has been reported to extend the life of this type of implanted reference electrode.\(^{75}\) Rather surprisingly, the most stable form of reference electrode for VIV is a bare Ag wire that can provide stable signals over weeks of recording;\(^{76}\) the exact nature of the chemical reversibility is not clear, but may involve either Ag/Ag\(^+\) or Ag/AgCl couples. Sample VIV data shown in sections 4.5 and 7.2 were recorded with this type of reference electrode.

The following description gives details of one approach to preparing auxiliary and reference electrodes for VIV, using Teflon®-coated silver wire (200-µm bare diameter). The Teflon® coating is removed from both ends to expose a 2–3 mm length of bare wire. An earth wire is also prepared using the same procedure. A gold connector is soldered to one end and the other end is gently manipulated, using a small tweezers, to produce a characteristic hook shape in the case of the auxiliary and earth. This enables them to be placed between the skull and dura (see section 6). The end of the reference is manipulated to produce a perpendicular kink about 1–2 mm from the end of the wire. This prevents the wire from penetrating beyond the cortical tissue. Once prepared, all electrodes (including the working electrodes) are inserted into a plastic socket via the gold pins (see section 6) and secured with dental acrylate. The design of various types of working electrodes for VIV is described below.

### 4.2 Platinum

Coated Pt wire normally forms the basis of Pt working electrodes used for VIV.\(^{21}\) Either disk (100–300 µm diameter) or cylinder (~1 mm length) electrodes can be generated simply by removal of selected segments of the insulation, usually Teflon®. Diameters as low as 15 to 25 µm have been reported,\(^{77,78}\) but in these cases additional mechanical support, usually a glass capillary, is required. To protect from fouling, Pt surfaces can be coated with a variety of membranes such as precast or cast cellulose acetate,\(^{79}\) recast or electrodeposited perfluorosulfonated ionomers,\(^{80}\) or electropolymerized films that can be as thin as 10 nm.\(^{81,82}\)

### 4.3 Carbon Epoxy

A mixture of carbon paste (see section 4.5) and epoxy resin, force-filled into a glass capillary (~50–200 µm in diameter) and heat cured, provides a robust carbon epoxy electrode (CEE) for implantation in brain tissue. In the unmodified form, CEEs show little discrimination between AA, metabolites and neuromediators and early reports using CEEs with chronoamperometry for voltammetric detection of DA and 5-HT in vivo may have been affected by changes in AA concentration.\(^{83,84}\)

Electrochemically pretreated, however, by the application of a potential high enough to electrolyze water, AA and catechol signals have been well-separated with pulse voltammetries, apparently by the cleaning,\(^{85}\) roughening and oxidation of the electrode surface.\(^{86}\) Anion-repelling polymer membranes (especially Nafton®) on the electrode surface that inhibit AA and metabolite access to the electrode\(^{87,88}\) have also been used to improve the selectivity of CEEs for DA.\(^{23}\) Although not widely used now for VIV, CEEs continue to be developed as forms of rigid carbon polymeric biocomposites.\(^{89}\)

### 4.4 Carbon Fiber

Prepared by sealing single\(^{90,91}\) or multiple\(^{92,93}\) strands of carbon fiber into glass\(^{94}\) silica\(^{95}\) or Teflon®\(^{96}\) capillaries, carbon fiber electrodes (CFEs) are the most commonly used electrodes for VIV, principally because of their small diameter (5–50 µm) and easily varied length (0 to 500 µm). Sealing the fiber into the support is the most critical step in the preparation of CFEs and this has been achieved by a variety of methods, including the use of epoxy resin and, more recently, by the electrophoresis of paint.\(^{95}\)

Armstrong-James and Millar\(^{90}\) and Ponchon et al.\(^{97}\) introduced CFEs in 1979, and their usefulness increased dramatically when it was demonstrated that resolution of AA (as peak 1) and catechol (as peak 2) could be achieved with pulse\(^{61,98,99}\) and staircase\(^{100}\) voltammetries following modification of the surface by application of either a triangular potential\(^{91}\) or constant current\(^{70,101}\) before use. Electrochemical and spectroscopic studies indicate that these treatments are likely to improve the performance of CFEs by increasing electron transfer rates\(^{102–104}\) and adsorption of analyte\(^{105,106}\) on the surface. Treatments have been explained in terms of a combination of electrode cleaning, increased area of active graphite edges from cracking, and oxidation of the surface.\(^{104,107,108}\) It appears that the important parameter of the treatment is not the applied potential, but the current density passed, and the most reproducible results have been obtained under galvanostatic rather than potentiostatic conditions.\(^{100,109}\) This factor may explain the difficulty some laboratories have experienced in producing good electrical treatment of CFEs, especially if the potentiotstat used was not designed for the relatively high currents associated with this process.\(^{110}\) Although electrochemical activation still remains the most common form of CFE treatment, laser\(^{102}\) heat\(^{104,111}\) and chemical\(^{112,113}\) treatments have also been successfully used. Other important factors shaping the effectiveness
of these modifications include the pH\(^{114,115}\) and the buffer ions\(^{102,116}\) of the treatment solution, phosphate buffer pH 7.4 being the most common medium.

Although electrical and other treatments of CFEs enable separation of AA and catechol signals, the problem of separating the two catechols (small DA and large DOPAC currents in DA-rich, NE-poor brain regions, such as dorsal striatum) is more difficult, but has been achieved using a number of different strategies. Nafion\(^{9}\) coating of either treated or untreated fiber disks or cylinders repels AA and DOPAC, and allows both K\(^{+}\)-evoked\(^{117,118}\) and electrically stimulated\(^{119,120}\) DA release to be observed, although AA and DOPAC may interfere with the detection of slower drug-induced changes in DA.\(^{74}\)

In addition to AA, DA and DOPAC detection, CFEs have also been used to monitor the 5-hydroxyindoles, 5HT and 5HIAA. By adjusting the electrical treatment parameters, the relative sensitivities and resolution of CFEs can be varied and a voltammetric peak (peak 3), containing contributions from 5HT, 5HIAA and UA, can be recorded in the ECF.\(^{121–125}\) In acute experiments shortly after implantation of the CFE, the main contributors to peak 3 are 5HIAA (about 70%) and UA (about 30%) in both brain striatum\(^{122}\) and spinal cord.\(^{126}\) Peak 3 recorded 7 days following implantation, however, appears to be due entirely to 5HIAA.\(^{127}\) See section 7.4 for further discussion of this phenomenon.

### 4.5 Carbon Paste

Carbon paste, prepared by thoroughly mixing carbon powder with either Nujol\(^{4}\) or silicone oil\(^{62}\) can be easily packed into cavities made by pulling the insulation over fine metal wires, producing disk electrodes of diameters as small as 160\( \mu \)m, although diameters of about 300\( \mu \)m have been generally used for VIV. A carbon/Nujol paste electrode with CV was used in one of the first reports of voltammetry in brain tissue with the aim of studying DA,\(^4\) and a single peak was observed in rat striatum, attributed mainly to the oxidation of AA. Decreasing the scan rate to 10 mV s\(^{-1}\) and semidifferentiation of the current later revealed three rather broad waves on the striatal voltammogram.\(^{128}\) Further developments of the technique by the use of computer-controlled equipment,\(^{129}\) silicone oil paste,\(^{62}\) an additional reduction of the sweep rate to 5 mV s\(^{-1}\), abandoning semidifferentiation, and subtraction of the background current recorded in situ, yielded CPE voltammograms consisting of three well-separated peaks in striatal tissue\(^{130}\) (see Figure 2).

Peak-shaped signals are obtained by this non-differential method due to both thin-layer behavior in the compartment around the implanted electrode\(^{66,131,132}\) and adsorption of the analytes.\(^{65,133}\) Because of the lack of clear resolution between AA and catechols by CPEs, a wide variety of techniques have been used to characterize the CPE signals recorded in rat striatum in vivo: theoretical analysis\(^{132}\) electrochemical studies in vitro;\(^{62,129}\) microinfusion of candidate substances\(^{129,134}\) and metabolizing enzymes\(^{133,135–137}\) beside electrodes implanted in brain tissue; lesions to striatal afferent pathways\(^{71,135,138}\) pharmacological perturbations using drugs with well-characterized actions\(^{71,134,136,139}\) and comparison with other in vivo techniques, such as microdialysis.\(^{133,140}\)

These experiments, reviewed recently,\(^ {64}\) indicate that peak 1 (see Figure 2) is due mainly to AA; moreover changes in the height of peak 1 result from variations in the extracellular concentration of AA, provided there is no significant shift in the relative potentials of peaks 1 and 2. When such potential shifts occur they are not due to electrocatalysis but to the algebraic combination of the AA peak (at the normal potential of peak 1) and the
catechol peak some 60 mV higher, and difference voltamograms can be used to analyze the changes in terms of fluctuations in the catechol concentration.\(^{129}\) Under most circumstances (some exceptions being stroke\(^{141}\) and death\(^{142,143}\)) these latter changes are mainly due to DOPAC, because the level of DA in striatal ECF has been estimated by a range of techniques to be less than 50 nM.\(^{72,144,145}\) The main component of peak 2 is UA with a minor contribution from 5HIAA when ~300 µm CPEs are used,\(^{133}\) whereas peak 2 recorded with 160 µm CPEs is due to 5HIAA almost exclusively.\(^{139}\) Changes in the height of peak 3 are directly proportional to changes in the extracellular concentration of methylated metabolites of DA. Normally this is HVA,\(^{71}\) but when MAO is inhibited pharmacologically, 3MT may contribute\(^{140}\) (see Figure 1).

The main advantage of CPEs is their stability over several months of recording in vivo.\(^{8}\) It appears that lipids present in the tissue remove pasting oil from the surface\(^{139}\) and reverse poisoning caused by proteins.\(^{76}\) This factor may also undermine the use of CPEs that have been chemically modified with lipophiles, such as stearic acid, for the detection of DA\(^{146,147}\) because such species can be removed from the electrode surface following contact with brain tissue,\(^{148}\) although this point is still a subject for debate.\(^{17}\) The principal disadvantage of CPEs is their comparative large size, and neurochemical studies have been limited to relatively large brain regions such as striatum,\(^{149–151}\) nucleus accumbens,\(^{151–153}\) cortex,\(^{154,155}\) pallidum\(^{156}\) and hippocampus.\(^{151,155,157}\) None of these brain areas can be considered an homogeneous array of cells – even the striatum consists of an array of substructures\(^{158}\) – and so the development of an electrode with the dimensions and sensitivity of CFEs and the stability of CPEs is an on-going objective for VIV.

### 4.6 Biosensors

A biosensor can be defined as a device that involves the immobilization of a sensitive and selective biological element on, or within close proximity of, an analytical detector. The range of components that have been used in the development of biosensors is extensive; typical examples include enzymes, plant and animal tissues, microbes and antibodies. The type of analytical detector employed is also wide ranging (e.g. electrodes, optical fibers and crystals) and is generally used to classify the biosensor. The fundamental principles, designs and wide ranging applications of biosensors have been described in detail in comprehensive reviews in the literature.\(^{16,159,160}\)

The primary reason for developing biosensors for applications in vivo is the ability to measure biologically important compounds that are either electroinactive or only poorly electroactive at analytically useful potentials. Such compounds include glucose, lactate and glutamate (see Table 1). Enzyme-modified electrodes, particularly amperometric devices, are the most thoroughly investigated sensors in the biosensor field. Their origin dates back to the first reported biosensor (for glucose) by Clark and Lyons in 1962.\(^{161}\) Prolific research on the development and applications of enzyme-modified electrodes over the intervening three decades has yielded sensors for a large variety of analytes, including glucose, ethanol, cholesterol, bile acids, purines and amino acids.\(^{159,160}\) However, despite the significant advantage of continuous real-time monitoring afforded by these electrochemical devices, only a small percentage have actually been used in vivo for chemical analysis in the living brain. This is primarily due to the many difficulties associated with performing direct measurements in such complex environment as brain ECF (see section 2.2). Important considerations include the immunological response to the implanted sensor, the presence of electrode poisons and endogenous interferences, restriction of mass-transport by brain tissue, effects of depletion, and the availability of suitable enzymes for the specific analytes of interest. The sensors that have been successfully used for VIV have all been amperometric flavoprotein oxidase-modified electrodes for either glucose, lactate, glutamate or choline.\(^{21}\)

The immobilization of the enzyme component onto the electrode surface has been achieved using various strategies. The most common methods include: direct physical adsorption; covalent bonding (e.g. via carbodiimide) and/or cross-linking (e.g. via glutaraldehyde); entrapment behind pre-cast (e.g. cellulose acetate), cast (e.g. polyurethane), and electrodeposited (e.g. Nafion\(^{®}\)) membranes; and more recently, entrapment within electrosynthesized polymeric matrices (e.g. polypyrrole and polyphenylenediamine).\(^{16,159,160}\)

The classic and most common enzyme-modified electrode is the glucose biosensor incorporating the oxidoreductase enzyme, glucose oxidase (GOx, isolated from *Aspergillus niger*, E.C. 1.1.3.4). This type of sensor has become the model system primarily due to the importance of glucose monitoring in the disease diabetes mellitus, and the fact that glucose determination in various body fluids, such as blood, plasma and urine, remains one of the most common analyses performed in clinical laboratories. Additionally, GOx has good substrate specificity, a high turnover rate, and excellent stability that makes it ideally suited for use in a biosensor.\(^{162}\) GOx is a flavin-containing enzyme that catalyses the oxidation of D-glucose in the presence of oxygen, producing hydrogen peroxide:
where FAD is the oxidized form of the prosthetic group, flavin adenine dinucleotide. The development of amperometric enzyme electrodes has focused on the measurement of the glucose signal generated by the reaction of the reduced enzyme (GOx/FADH₂), and can be categorized broadly in terms of first, second and third generation devices.

Classic or ‘first generation’ enzyme-modified electrodes involved monitoring either the consumption of oxygen,⁹¹ or the formation of hydrogen peroxide.⁹² These devices suffered from a number of drawbacks including fluctuations in response due to low and/or variable oxygen tension, and interference from endogenous electroactive species due to the large applied overpotential (typically +700 mV versus SCE) required for hydrogen peroxide oxidation. Despite this, hydrogen peroxide detecting sensors still remain the most common type of enzyme-modified electrode, and over the years a number of attempts have been made to overcome these problems. In particular, nonphysiological electron transfer mediators, immobilized on the electrode surface or within the enzyme layer, have been used to replace oxygen, the natural or physiological enzyme mediator. Such artificial mediators must exhibit several important characteristics: reversible electron transfer kinetics at the electrode surface, and rapid homogeneous kinetics for the enzymatic reaction in solution; possess a low overpotential for regeneration of the oxidized form of the mediator; and be stable in both oxidized and reduced forms. Many such redox mediators have been investigated and found to meet these criteria. Typical examples include ferrocinium ions, quinones, ferrocyanide, ruthenium compounds and tetrathiafulvalene.⁹³ However, although these ‘second generation’ devices have the advantage of a low operating potential, and elimination of oxygen from the reaction scheme, they do suffer from a number of problems. These include leaching of mediator from the electrode surface or enzyme layer,⁹⁴ toxicity in biological tissues,⁹⁵ and electrochemical interference, e.g. oxidized ferrocenes can be reduced by AA.⁹⁶ Additionally, the complete insensitivity to oxygen tension sometimes claimed for this type of sensor has been questioned for certain mediators.⁹⁷ More recently, another form of mediated system that has found widespread usage is that of entrapping the enzyme in a redox polymer (e.g. poly(ethylene glycol) diglycidyl ether) that can serve as both the mediator and enzyme immobilization matrix.⁹⁸,⁹⁹

Eliminating the mediator from the reaction scheme and achieving the simplest approach of direct electron transfer from the reduced enzyme to an electrode has proved extremely difficult. This is generally accepted to be because the distance between the FAD active site and the electrode is such that direct electron transfer to the electrode takes place slowly or not at all. Consequently, very few mediatorless or ‘third generation’ enzyme electrodes have as yet been devised. The first report of such a device was by Albery et al.¹⁰⁰ using one-dimensional organic conducting salt electrodes, e.g. tetrathiafulvalenium tetracyanoquinodimethanide (TTF⁺TCNQ⁻), to eliminate the mediator from the reaction scheme. However, the mechanism of electron transfer at these organic salt electrodes is now generally accepted as being a mediated process involving species such as TCNQ³.¹⁰¹ Since then, successful direct electrical communication between GOx and an electrode surface has been claimed by several groups using a variety of techniques. These include direct electron transfer between covalently bound GOx and a cyanuric chloride modified graphite electrode,¹⁰² between GOx immobilized on glassy carbon modified by aminophenylboronic acid,¹⁰³ and between GOx immobilized via adsorption and a variety of cross-linking reagents onto platinized carbon paper electrodes.¹⁰⁴ Urea has been used to modify the enzyme structure by opening the active site, thus making it more accessible to a ferrocyl acetamide-modified electrode, composed of arrays of electron-transfer relays.¹⁰⁵ This type of chemical modification of the enzyme has led to the development of ‘electrically wired’ enzymes.¹⁰⁶ A hydrophobic interaction between GOx and TTF molecules has also been reported with the resultant opening of a direct path of electrical communication between a Pt electrode and the flavin redox center.¹⁰⁷

Finally, before a biosensor can be used reliably in vivo it is necessary to perform a detailed characterization in vitro of the device. Such a characterization typically includes studies of sensitivity, linear calibration range, response time, interference properties, and stability.¹⁰⁸,¹⁰⁹ However, it is also very important that a detailed in-vivo characterization be performed in the target environment before the sensor is used in direct physiological investigations.¹¹⁰ This is to ensure that the properties obtained in the artificial in-vitro environment are maintained in the more complex living biological milieu.

5 VOLTMETRIC TECHNIQUES USED IN VIVO

In VIV one is usually interested in how the concentration of a particular neurochemical is changing with time.
on a scale from milliseconds to days. The choice of technique will therefore be restricted by the time resolution needed, in addition to other factors such as how well the working electrode can discriminate between the different electroactive species present in the ECF. Since the vast majority of substances of interest in VIV studies undergo oxidation, rather than reduction reactions, the descriptions that follow will be for oxidative voltammetry. The forms of voltammetry most often used for neurochemical analysis in vivo have been reviewed.\(^{8–22}\)

Different forms of voltammetry can be categorized on the basis of the time resolution achieved for detecting changes in the concentration of species in the ECF. Fast techniques with resolutions of the order of seconds or less are chronoamperometry, fast cyclic voltammetry (FCV), differential pulse amperometry (DPA) and constant potential amperometry (CPA), and these methods are generally used to detect stimulated changes in neurotransmitter overflow. Slow techniques with time resolutions of the order of several minutes are linear sweep voltammetry (LSV), staircase voltammetry (SCV), differential pulse voltammetry (DPV) and differential normal pulse voltammetry (DNPV) at low scan rates.\(^{13,21}\) The latter are usually used in studies of neurochemical metabolites as well as AA and UA. The minimum interval between scans is limited not only by the sweep time but also by the time taken for the concentration of the electrolyzed species in the compartment around the implanted electrode tip to return to its unperturbed value by means of tortuous diffusion through the tissue matrix (see Figure 2).\(^{69}\)

### 5.1 Chronoamperometry

This is one of the simplest forms used for VIV and was one of the first.\(^{83}\) Initially, the potential is held at a sufficiently low level where no oxidation occurs. A square pulse is then applied for between typically 100 ms and 1 s to a value corresponding to a high overpotential for the particular analyte of interest, and the current sampled close to the end of the pulse (usually integrated over a short time interval) where the ratio of faradaic to charging current is large. Because the current sampled close to the end of the pulse (usually integrated over a short time interval) where the ratio of faradaic to charging current is large. Because the initial currents associated with chronoamperometry are among the largest produced by VIV, it is interesting to note that simultaneous recording of nerve cell firing during this,\(^{181}\) and other relatively high current forms of VIV,\(^{182,183}\) indicate that voltammetry in nervous tissue does not appreciably interfere with the normal electrical properties of neurons.

Although chronoamperometry has an advantage for VIV of good temporal resolution (up to 200 ms\(^{184}\)), a major limitation in its simplest form is the inability to differentiate between compounds with similar oxidation potentials. Thus, because AA tends to oxidize at least to some extent at lower potentials than monoamine neuromediators at unmodified electrodes, early in-vivo chronoaomperometric data may have been contaminated with contributions from AA. Two later innovations have revived interest in chronoamperometry: the use of anion-repelling polymer membranes (especially Nafion\(^{66}\)) on the electrode surface that inhibit AA and metabolite access to the electrode; and the development of reverse-pulse chronoaomperometry that allows discrimination between different species oxidized based on the ratio of their oxidation/reduction response.\(^{21,24,185–187}\)

### 5.2 Linear Ramps

The general feature of this group of voltammetric techniques is the application of an essentially linearly increasing potential from an initial value where no oxidation occurs to a final value at a fixed scan rate (5 to 100 mV s\(^{-1}\) for VIV), allowing the sequential oxidation of a range of analytes. The simplest example is LSV where a truly linear (from an analog device) potential is used. Because many VIV studies now use computer-controlled digital equipment,\(^{72,100,129}\) the potential is incremented in discrete steps so that SCV is obtained. In studies with CFEs, where relatively large steps are involved (10 mV), a differential form of analysis is used where the current measured on a given step is subtracted from the next value to give a peak-shaped voltammogram with cylindrical microelectrodes.\(^{100,188}\)

If the potential is scanned back to the initial value after reaching the maximum point, the technique is CV. This approach is used very rarely at slow scan rates for VIV because most of the oxidation reactions are chemically irreversible in vivo.\(^{4}\) However, FCV at sweeps of about 300 V s\(^{-1}\), where the oxidized form is reduced before the following chemical reaction can occur appreciably, is now widely used for VIV because the different components in the ECF can be distinguished on the basis of the shape of their oxidation–reduction currents.\(^{18,22,120,189–195}\)

The main advantage of the slow ramp techniques is that a number of separate signals associated with different neurochemicals of interest can be obtained in the same voltammogram using either CPEs (see Figure 2) or CFEs.\(^{21}\) A consequent disadvantage is the time taken to sweep the potential (up to 2 min at 5 mV s\(^{-1}\)) as this restricts the time resolution of the concentration determination to a minimum of about 5 min for 5 mV s\(^{-1}\)\(^{157}\) and 2 min for 100 mV s\(^{-1}\)\(^{100}\) to allow for the slow recovery of ECF levels of analytes electrolysed from the compartment around the electrode tip. For FCV the situation is reversed because a good time resolution of 100 ms has been achieved.\(^{196}\) but only
a single substance can be detected under the conditions of any given experiment.

5.3 Pulsed Techniques
There is a wide variety of pulsed voltammetric techniques available. DPV, where a pulse of fixed amplitude is superimposed on a linearly increasing ramp, and the current, sampled just before the pulse, is subtracted from that measured close to the end of the pulse; normal pulse voltammetry (NPV) in which a pulse of increasing magnitude is applied relative to a constant resting baseline potential, and the current sampled near the end of the pulse; DNPV, where a double pulse of fixed potential difference is applied with increasing amplitude from a constant baseline; and DPA, where a double pulse of fixed potential difference is applied at fixed amplitude and the difference in current at the two pulses plotted as a function of time.

The first pulsed voltammetric form for VIV with carbon electrodes was NPV. DPV, however, has been widely used, although DNPV is also common and DPA has been used more frequently in recent reports. The main advantage of the pulse approach is that the different parameters of the potential form – pulse amplitude, duration and separation – can be adjusted to provide maximum resolution of the target analyte based on differences in its kinetic and adsorption properties on the electrode. In addition, capacitance currents can be minimized if the subtraction is carried out before the amplification stage. Square wave voltammetry that involves sequential measurement of oxidation and reduction currents has not been widely used in VIV, but has an advantage that good peak resolution can be achieved at relatively fast scan rates of about 125 mV s\(^{-1}\) compared with about 10 mV s\(^{-1}\) for DPV and DNPV.

More recently, differential multipulse amperometry (DMPA) has been developed and applied to neurochemical studies. Here potentials determined using DNPV are used to construct a voltage profile consisting of four short pulses (two pairs) repeated indefinitely. The pulse potentials were chosen so that the difference in amperometric response between the first two pulses was due to DA, whereas 5HT was detectable using the second pair. Sub-second detection of these two neuromediators appears possible using this approach, although the data available to date is limited.

5.4 Constant Potential Amperometry
In CPA, the current is monitored essentially continuously at a fixed potential where the redox reaction of the analyte of interest occurs, usually under diffusion-limiting conditions. This form has recently been used for VIV because of its high time resolution, but applications are limited to situations where the oxidation of only one analyte can be assumed with some certainty as in the detection of AA at low potentials and catecholamines following stimulation of specific pathways in vivo and from isolated cells in vitro. The specificity of biosensors makes them ideal devices for use with CPA, and this will be discussed separately below.

6 SURGICAL PROTOCOL FOR VOLTAMMETRY IN VIVO EXPERIMENTS

6.1 General Considerations
Before carrying out any surgical procedure it is important to think carefully about the facilities that are available and whether they are adequate for what is to be achieved. Implantation of microelectrodes for VIV requires good aseptic conditions with proper sterilization of equipment and instruments. Surgical procedures should be as atraumatic as possible. It is important to learn how to handle surgical instruments correctly and to avoid damaging tissues by grasping them with excessive force or with inappropriate instruments. Surgery on small animals such as rodents should be performed in a designated surgery room. A recovery area should be provided where animals can be taken after surgery for postoperative care and observation while recovering from the procedures and anesthetic.

Male Sprague–Dawley rats weighing between 200 and 300g (mature young adults) are generally used in VIV experiments. The animals are usually housed in a temperature-, humidity- and light-controlled environment, with free access to food and water. Sample protocols for VIV experiments are described in the following sections.

6.2 Anesthesia
Successful anesthesia does not depend simply on the types of drugs, doses, and routes of administration used. A good standard of animal care must also be maintained, both pre- and postoperatively, including reduction in stress and provision of pain control. All these factors must be taken into account when designing an anesthetic regime. A typical regime used to induce anesthesia for implanting microelectrodes is as follows. A combination of the opiate analgesic fentanyl (0.32 mg mL\(^{-1}\))/fluanisone (Hypnorm, 0.1 mg mL\(^{-1}\)) and the benzodiazepine midazolam (Hynovel, 5 mg mL\(^{-1}\)), mixed 1:1:2 with sterile water, is injected intraperitoneally (i.p.) at a volume of
3.3 mL kg\(^{-1}\). This results in surgical anesthesia within 4–5 min, that is maintained for the 45 min of the surgical procedure. Both corneal and hind limb withdrawal reflexes are tested to confirm the level of surgical anesthesia. In order to complete the cementing process at the end of surgery (see section 6.3) 1–3 mg kg\(^{-1}\) of midazolam is administered intramuscularly. On completion of the surgery and cementing, an injection of naloxone (0.1 mg kg\(^{-1}\), i.p.) is given to reverse the opiate effect and prevent respiratory depression. Post-operative analgesia is provided in the form of a single injection (0.1 mg kg\(^{-1}\), subcutaneously) of Vetergesic (buprenorphine) given immediately following the surgery.

### 6.3 Surgery and Recovery

Once surgical anesthesia is established, the animal is placed in a stereotaxic frame. Body temperature is maintained at 37°C throughout surgery with an isothermal heating pad. A midline incision 1–2 cm in length is made to reveal characteristic skull markings, bregma and lambda, which are used as coordinate reference points. The underlying muscle and fascia are scraped away and the skull levelled between bregma and lambda. A schematic of a typical surgical and implanting process is shown in Figure 3(b). Artery clamps are used to hold the incision open. With the aid of a dissecting microscope, small burr holes are made in the skull to enable implantation of small support screws and the recording electrodes. The latter are positioned in the target brain area according to coordinates obtained from a stereotaxic atlas. For example, for rat striatum (left and right) that is the most widely studied region for VIV, the coordinates are: anterior/posterior, +1.0 mm from bregma; mediolateral, ±2.5 mm from bregma; and dorsoventral, −5.0 mm from the dura. The reference electrode (8T Ag wire, 200-μm bare diameter) is placed in the cortex, the auxiliary electrode (8T Ag wire) between the skull and dura, and an earth wire (8T Ag wire, applicable with plastic animal bowls) attached to one end of midastratal, i.p.) is given to reverse the opiate effect and prevent respiratory depression. For example, for rat striatum (left and right) that is the most widely studied region for VIV, the coordinates are: anterior/posterior, +1.0 mm from bregma; mediolateral, ±2.5 mm from bregma; and dorsoventral, −5.0 mm from the dura. The reference electrode (8T Ag wire, 200-μm bare diameter) is placed in the cortex, the auxiliary electrode (8T Ag wire) between the skull and dura, and an earth wire (8T Ag wire, applicable with plastic animal bowls) attached to one end of

### Figure 3
(a) Schematic representation of the electrode assembly suitable for VIV. A gold connector is soldered to one end of each electrode. Each electrode is inserted into a six-pin Teflon® socket via the gold pins. This socket, which is secured to the skull with dental acrylic after implantation, can then be connected through a flexible screened six-core cable, mounted through a swivel (allowing free movement) above the animal’s head, to the electrochemical instrumentation. The design of the various types of electrodes is described in section 4. (b) Schematic representation of a surgical and implanting process: (i) A midline incision 1–2 cm in length is made over bregma (cross) and the underlying muscle and fascia scraped away. Artery clamps are used to hold the incision open. Small burr holes are made in the skull to enable implantation of support screws and the recording electrodes. (ii) Positioning of the reference electrode (200-μm bare Ag wire) in the cortex. (iii) Positioning of the auxiliary electrode or earth wire (200-μm bare Ag wire) between the skull and dura. The auxiliary may also be simply attached to one of the support screws.
of the support screws. All electrodes are secured with dental acrylate. The clamps are removed and a second application of acrylate serves to close the incision and to further stabilize the electrodes.

Once the dental acrylate has sufficiently hardened the animal is removed from the stereotaxic frame and returned to its home cage to recover, with its body temperature controlled while the analgesic effect of the opiate persists. At the end of this period, if signs of pain are observed, an additional injection of buprenorphine is given subcutaneously. The animal room is normally maintained on a 12/12 hour light/dark cycle.

6.4 Assessment of Animal Health
All animals should be monitored routinely following surgery for any signs of pain or distress. During the recovery period food and water should be freely available. A post-operative record should be kept that includes information on urine, faeces, food and water intake, drugs administered, and stress scoring. This practice ensures that only healthy, pain free animals become experimental subjects. Generally, a post-surgery period of 24 h is necessary and sufficient for recovery.

6.5 Experimental Conditions
There are two main categories of experimental conditions for VIV. The first, in terms of technical simplicity, is when recording takes place while the animal is still in the stereotaxic frame under the influence of anesthetic; this is termed an ‘acute’ preparation. The following factors must be taken into account when analysing data recorded under these conditions: concentrations of analytes may be effected by acute tissue damage; the BBB may not be intact; and the effects of the specific anesthetic agents on the concentration of target analytes. (21)

The second, and now more common, ‘chronic’ preparation involves allowing the animal to recover from anesthesia (see section 6.3). Implanted electrodes can be connected to the recording equipment through, for example, a six-pin Teflon® socket (see Figure 3a), and a flexible screened six core cable, that is mounted through a swivel above the rat’s head. This arrangement allows relatively free movement of the animal. Possible complications with this preparation include gliotic reaction by the tissue and perturbations of the chemical environment around the implanted electrodes (see section 7.4).

6.6 Hazard Assessment
As with all procedures in a laboratory, it is now considered wise to undertake and document a safety hazard assessment of the materials and actions involved before carrying out the procedure, in which the hazards are identified, the risks assessed and control measures put in place to minimise the risks. Particular hazards for VIV experiments include: being bitten and contracting disease; developing allergic reactions in the respiratory system and skin; and being injured by scalpels and needles. Control measures associated with these hazards should include the careful handling of animals, appropriate inoculation of personnel, the wearing of face masks and gloves, and the careful use and disposal of sharps.

7 DETECTION OF SUBSTANCES IN BRAIN EXTRACELLULAR FLUID
The brain operates at a range of levels – molecular, cellular, regional and as a whole – and the choice of voltammetric technique depends to a large extent on what one wants to study. Microdialysis has also been developed to sample the ECF for neuroactive species, usually followed by separation with high-performance liquid chromatography (HPLC), and either electrochemical or spectroscopic detection (see section 8). An advantage of microdialysis is the wide range of compounds: neuromediators, metabolites, amino acids, drugs, etc. that can be collected in each sample and separated reliably using recent advances in HPLC technology. (210) The main disadvantages of dialysis are the relatively large probe size available (minimum ~ 200 µm) and the poor time resolution, ranging from 2–10 min, although about 1 min has been achieved recently with capillary electrophoretic separation. (211) Although voltammetry has been limited until recently to electroactive analytes (a limitation that is being overcome with the development of enzyme-modified electrodes; see section 4.6), its advantages of small probe size and high temporal resolution, which have been achieved in many studies, allow investigations not possible with microdialysis.

The vast majority of neurochemical studies employing voltammetry have been carried out using rats, although there are examples of other species being investigated, such as snails, (212) turtles, (213) mice, (214) hamsters, (215) guinea-pigs, (216) cats, (217) sheep, (218) and non-human primates. (219)

7.1 Electroactive Neuromediators
Although brain slices offer a convenient and effective way of manipulating individual neuronal pathways to study their pharmacology and physiology, the function and response of a given projection in vivo depends to a large extent on the myriad of connections to and from other pathways, many of which are severed in the slice.
VOLTAMMETRY IN VIVO FOR CHEMICAL ANALYSIS OF THE LIVING BRAIN

Voltammetry has therefore been used in vivo to investigate neuromediator function in the context of the living brain, and in many cases its relationship to behavior.\(^{(21)}\) However, because the baseline extracellular concentrations of electroactive monoamine neuromediators are of the order of nanomolar\(^{(7,14,15,21,19)}\) (Table 1) due to efficient reuptake mechanisms\(^{(210)}\) (Figure 1), many of the techniques available are not sensitive enough to detect these levels. A number of approaches have been used, therefore, to monitor artificially high levels of neuromediator overflow in the ECF, mainly in acute, anesthetized preparations.

High doses of the MAO inhibitor, pargyline, greatly reduce DOPAC levels in the ECF (see Figure 1) so that peak 2 recorded with CFEs and DPV is abolished.\(^{(61)}\) The introduction of DNPV,\(^{(200)}\) which shows a higher sensitivity for DA, revealed a small DA signal close to the potential of peak 2 in pargyline-treated rat striatum, and later the development of DPA\(^{(99)}\) allowed the detection of DA with high time resolution in a number of brain regions under similar conditions.\(^{(214,220,221)}\)

In other approaches, chronoamperometry, FCV or CPA with CFEs has been used to monitor stimulated DA\(^{(22,195,222,223)}\) and NE\(^{(7,205,224)}\) release in a number of brain areas.\(^{(21)}\) A successful model based on release and uptake parameters\(^{(225)}\) has been used to understand the relationship between release and stimulation frequency for the dopaminergic nigrostriatal pathway, and how the effectiveness of drugs used clinically, including neuroleptics, can depend on firing rate.\(^{(144,226)}\) In contrast, baseline (non-stimulated) ECF levels have been measured for DA as low as 2 nM in striatum,\(^{(219)}\) and for 5HT\(^{(227)}\) in frontal cortex (5 nM) and raphe nuclei (10 nM) using Nafion\(^{\circledR}\)-coated electrochemically-treated CFEs with DPV, and an important study with these electrodes has shown that extracellular concentrations of 5HT and 5HIAA are not necessarily correlated.\(^{(228)}\) Although promising, these electrodes have not found widespread use for VIV, presumably due to reproducibility and stability problems.

Until recently, these approaches had a limitation that anesthesia was involved during the VIV recordings. A range of general anesthetics are known to affect the firing rate and responsiveness of neurons and the release, uptake and metabolism of a variety of neuromediator substances. This is not surprising because the widely distributed γ-aminobutyric acid (GABA)-receptor/chloride-channel complex may be a common mediator in some aspects of anesthetic action.\(^{(229)}\) Indeed, specific examples of different (sometimes opposite) VIV results in the presence and absence of anesthetics have been reported.\(^{(149,157,230)}\) The finding, therefore, that basal concentrations of DA and 5HT can be detected with mathematical deconvolution\(^{(231)}\) of the DNPV signals recorded with electrochemically treated CFEs in unanesthetized, freely moving rats is an important advance in VIV.\(^{(21)}\) More recently, replaceable electrode systems and other strategies have been applied to monitor behaviorally-related changes in the concentration of monoamine neuromediators with CFEs, including sexual behavior,\(^{(232)}\) free-choice novelty,\(^{(233)}\) and electrical self-stimulation of brain reward centers.\(^{(195)}\)

### 7.2 Electroactive Neuromediator Metabolites

A principal aim of VIV is the generation of a signal as closely related as possible to neuromediator release in the synapse. An important question that has yet to be resolved is which species in the ECF is the closest reflection of synaptic release. The main candidate is the neuromediator itself overflowing into the ECF (see Figure 1). However, there are populations of neuromediator receptors outside the synapse and transmitter in the ECF may have a different function to that in the synapse. Moreover, there appear to be cases where environmental stimulation (e.g. presentation of food after a fast) causes activation of nigro-striatal DA cells without associated increases in striatal ECF DA levels.\(^{(234)}\) The link between extracellular metabolite levels and release rate is also problematic. In the case of the monoaminergic systems, DOPAC and 5HIAA are more likely to reflect synthesis rate than release (see Figure 1). However, COMT (one of the enzymes required for HVA production) is located outside the nerve terminal\(^{(235)}\) (see Figure 1). It has been suggested, therefore, that HVA may be a better index of DA release than DOPAC, and that HVA is a fair index in the absence of drugs, at least on a timescale of minutes.\(^{(13)}\)

A principal advantage of some metabolite signals is that they are stable over several days of recording with the same electrode, and therefore allow investigation of the relationships between neurochemical events and observed behavior over extended periods.\(^{(76)}\) A disadvantage is that changes in metabolite concentrations are much more sluggish than that of the corresponding neuromediator with lags of up to 30 min in the peak responses.\(^{(236)}\) The main VIV techniques used to monitor neuromediator metabolite levels in the ECF are CFEs with either SCV, DPV or DNPV (DOPAC as peak 2 and 5HIAA as peak 3) and CPEs with SCV (HVA as peak 3; see Figure 2). The CFE 5HIAA signal has been used to detect 5HT metabolism in the suprachiasmatic nuclei, raphe nuclei and hypothalamus over the sleep/wake cycle, and as a result of stress.\(^{(21)}\)

Diurnal variations in DA metabolism using the CPE HVA signal have been recorded in frontal cortex, nucleus accumbens and striatum and correlated with simultaneously monitored motor activity (Figure 4). Rats are nocturnal and show a high level of locomotion during the dark period. Electrochemical detection of HVA...
shows that, associated with this high activity phase, DA transmission in certain forebrain areas is also elevated. Correlation analysis indicates that DA transmission in the latter two brain structures, but not in frontal cortex, is closely involved in motor behavior. This correlation can be disrupted for striatal, but not accumbens, HVA by valium-type anxiolytic drugs such as the benzodiazepine, flurazepam. Changes in HVA associated with trained lever-pressing behavior have also been reported for striatum and nucleus accumbens.

7.3 Ascorbic Acid

With its high concentration and ease of oxidation, AA is probably the simplest molecule to detect and monitor in brain ECF using VIV techniques. Microdialysis methodologies, however, are not as fortunate in that they appear to have difficulty recovering and detecting changes in brain AA. This may be due to the presence in brain tissue of non-dialysable dehydroascorbate reductase that normally protects AA from oxidation in the ECF, and to the oxidation of AA in the buffer, catalysed by trace amounts of heavy metal ion impurities. These factors, together with the continuous depletion of ECF AA caused by perfusion, and the difficulty in separating AA successfully from the solvent front at the HPLC stage, may explain such analytical difficulties.

Voltammetric AA signals have revealed that the extracellular concentration of AA in discrete brain areas of awake animals changes with the animal’s behavior...
and responds to the administration of drugs. On the basis of experiments in vitro with synaptosomes, a model relating AA in the ECF with the uptake of excitatory amino acids through a heteroexchange mechanism has been proposed to explain these variations.\textsuperscript{[241]} The in vivo applicability of the model has been tested by a number of independent laboratories using a variety of lesion, stimulation, microinfusion and other pharmacological experiments, and so far has not been invalidated.\textsuperscript{[63,157,242–245]} It remains to be seen, however, whether this idea will survive more detailed testing in vivo, and whether AA will prove a useful tool for investigating in vivo the functions of glutamate, a ubiquitous neurotransmitter in the CNS.

### 7.4 Uric Acid

The origin and significance of changes in brain extracellular UA levels are not clearly understood, not least because the concentration of UA in the ECF depends to a great extent on the experimental conditions.\textsuperscript{[246]} Until recently it was believed that xanthine oxidase, the enzyme involved in the metabolism of hypoxanthine to UA, was not present in brain tissue and thus there have been few reports on the production and significance of this purine metabolite in the CNS. There is now, however, direct evidence that UA is produced in the mammalian brain. Furthermore, the use of in vivo monitoring techniques has shown that, in addition to spontaneous diurnal variations, a number of different stimuli give rise to changes in the extracellular concentration of brain UA, including: electroconvulsive shock; ischemia; systemic and intracerebral administration of drugs; feeding and drinking behavior; and motivated lever pressing.\textsuperscript{[246]} It appears, however, that the concentration of UA in brain ECF depends markedly on the size of the probe used and on the length of time the probe is in contact with the tissue.\textsuperscript{[139]}

Thus, a possible explanation has emerged for the apparently paradoxical results for UA and 5HIAA obtained with CPEs and CFEs. For several hours after an electrode is implanted the concentration of 5HIAA and urate are similar in the low micromolar range. However, the vast majority of CPE data have been recorded in awake freely-moving animals several days following implantation. With large CPEs (320-μm diameter), the concentration of UA increases to about 50 μM by 24 h after surgery and remains high for months; peak 2 is much larger compared with the acute condition and reflects mostly (about 90%) UA.\textsuperscript{[133]} When chronically implanted small electrodes are used such as CFEs or 160-μm diameter CPEs, the low level of UA observed under acute conditions actually decreases to below the limit of detection (about 1 μM\textsuperscript{[127,139]}). This phenomenon appears to be linked to the lesser extent of glial reaction to the smaller electrodes, and suggests that the low micromolar level of UA detected in the ECF under acute conditions may arise from leakage across the damaged BBB.\textsuperscript{[246]}

It is unclear whether extracellular UA reflects glucose utilization or neuromediator adenosine metabolism, although the weight of evidence to date favors the latter.\textsuperscript{[246]} Changes in the concentration of UA detected in the ECF under acute conditions (including studies using removable electrodes and dialysis cannulae in awake animals) may reflect variations in blood flow, because the BBB is damaged temporarily and blood contains relatively high UA levels. For chronically implanted large probes (>160-μm diameter), tissue reaction results in the extracellular concentration of UA being significantly higher than normal. One import of these data is that tissue perturbation caused by the implant is highlighted, as is the need to continue to develop small stable in vivo probes.

### 7.5 Dioxygen

Molecular oxygen was one of the first substances detected voltammetrically in vivo, both in brain\textsuperscript{[99,60]} and peripheral tissues,\textsuperscript{[247]} using noble metal and carbon electrodes that continue to be the electrode materials of choice for this analyte.\textsuperscript{[180,248–250]} The spread of mean concentrations reported for oxygen in cerebral tissue is quite tight, ranging from 40 μM\textsuperscript{[251]} through 50 μM\textsuperscript{[252]} and 60 μM\textsuperscript{[253]} to 80 μM\textsuperscript{[254,255]} The anatomical distribution of concentrations reported within the brain is wide, however, depending on the depth of penetration of the sensor into the tissue\textsuperscript{[256]} and the heterogeneity of the tissue.\textsuperscript{[251,257]} Brain tissue oxygen responds to a range of perturbations including electrical stimulation\textsuperscript{[254]} and neuromediator release,\textsuperscript{[258]} with more rapid turnover in cerebral cortex compared with other brain areas.\textsuperscript{[252]} There is good evidence that oxygen levels in brain ECF are positively and strongly correlated with cerebral blood flow,\textsuperscript{[198,259,260]} and it is now possible to monitor continuous brain tissue oxygen, carbon dioxide, pH, and temperature with simultaneous recording in the blood, using multisensor probes.\textsuperscript{[261]}

### 7.6 Nitric Oxide

NO is a relatively recently recognized neuromediator responsible for a variety of physiological responses,\textsuperscript{[262–264]} and initial attempts at its electrochemical detection in biological tissues have been reviewed.\textsuperscript{[262,265–267]} One of difficulties associated with detecting this free radical is its short half-life (<1 min) in tissues containing oxygen, and informal feedback from users of NO sensors (including commercial ones) suggests dissatisfaction with their...
7.7 Glucose and Lactate

As outlined in section 4.6, the first reported biosensor was a glucose sensor developed by Clark and Lyons in 1962.\(^{161}\) Despite the prolific research on such devices since this initial work, it was not until the mid-1970s that biosensors for direct applications in the living brain were reported. A glucose biosensor developed by Silver and co-workers was one of the first enzyme-modified electrodes demonstrated to be suitable for insertion into brain tissue.\(^{277}\) The electrode was prepared by simply dipping a 0.1-µm diameter Pt-coated glass micropipette electrode into an aqueous solution of GOx. The electrode, operated at +600 mV (versus Ag/AgCl), had a response time of 2–3 s that later increased to >30 s when a protective nitrocellulose membrane was added. Because these were early first generation hydrogen peroxide detecting devices, there were difficulties in the quantification of the glucose concentration arising from fluctuating oxygen and/or AA concentrations.

Later, Boutelle et al. constructed a very stable GOx-modified electrode, based on the TTF\(^{+}\)TCNO\(^-\) electrodes of Albery et al.\(^{70}\) for applications in brain tissue.\(^{278}\) GOx was immobilized by adsorption from solution. The electrode (250 µm) was held at 0 V (versus Ag/AgCl) and the signal from AA was found to decrease following both enzyme adsorption and implantation into brain tissue. Additionally, a differential method (involving the subtraction of the current recorded at an adjacent denatured enzyme electrode) was employed to minimize any possible interferences from fluctuating levels of AA. The response time of the sensor was of the order of 20 s, and no dramatic degradation of response was observed following 6 h periods of use in brain tissue. These biosensors were used to monitor glucose in the brains of freely moving rats and were shown to be capable of monitoring changes in glucose following a local application of insulin.

More recently, Silver and Erecinska have continuously monitored extracellular glucose in the brains of anesthetized rats in acute experiments with two types of substrate-specific microelectrodes (tips < 1 µm) in a number of different physiological and pathological conditions.\(^{279}\) Electrodes used in normoxic brain were needle electrodes polarized at +600 mV (versus Ag/AgCl) and prepared by electrodeposition of Pt-black on gold or Pt surfaces. The enzyme was immobilized by dipping in a solution of GOx, air-dried and cross-linked on the metal with glutaraldehyde. Finally, the tips were coated with four thin layers of cellulose diacetate, dried and dipped in a solution of ascorbate oxidase (to reduce AA interference). In hypoxic studies, mediator glucose electrodes were used with ferrocene (E\(^0\) = +165 mV versus SCE) as the electron acceptor. Extracellular glucose levels were shown to increase in hyperglycemia and decrease in hypoglycemia, paralleling changes in blood sugar. Increased neuronal activity, and in particular spreading depression, evoked triphasic alterations in the extracellular glucose concentration. Limitation in oxygen supply (hypoxia) led to a decline in the extracellular concentration of glucose with decreases to undetectable levels seen in ischemia despite the use of mediator electrodes. The extracellular concentration of glucose was estimated at 2.4 mM, in contrast to a value of 0.5 mM obtained using quantitative microdialysis.\(^{280}\)

The electrochemical polymerization of a selective poly(o-phenylenediamine) (PPD) layer onto Pt electrodes has also recently been reported to produce interference-free sensors having a high enzyme activity and a fast response time (about 1 s), making them ideally suited to detecting analytes directly in brain ECF.\(^{179,180}\) These sensors are generally prepared quite simply by potentiostatic polymerization from an enzyme/monomer mixture and operated at +700 mV (versus SCE) to detect the enzymatically produced hydrogen peroxide. Lowry and co-workers have reported a detailed characterization of Pt/PPD/GOx biosensors (125 µm) both in vitro\(^{179}\) and in vivo in the striatum of freely moving rats.\(^{180}\) Confirmation that these biosensors respond to changing glucose levels in vivo was obtained by i.p. injection of...
insulin and local administration of glucose (via an adjacent microdialysis probe). Interference studies involved administering AA and subanesthetic doses of ketamine i.p. Both resulted in increased extracellular AA levels with ketamine also increasing oxygen. No significant change in the Pt/PPD/GOx signal was observed in either case indicating that changes in AA and oxygen, the principal endogenous interferences, have minimal effects on the response of these first generation biosensors. They also exhibited excellent stability in vivo and have been used continuously under chronic conditions (14 days). These results were attributed to a pre-implantation conditioning procedure that helped overcome the general problem of loss of sensitivity (usually between 20–50%) following implantation. Furthermore, it was confirmed that depletion of analyte by the sensor was not a problem by examining the effects of perfusion, via an adjacent microdialysis probe, of drugs such as veratridine, that increases energy metabolism by stimulating Na+/K+-ATPase. The same group also implanted combined biosensors and microdialysis probes into the striatum of freely-moving rats to determine the ECF concentration of glucose using a modification of the Lönnroth no-net-flux quantitative microdialysis technique. A value of about 0.35 mM was obtained that is in good agreement with the value of 0.47 mM determined using microdialysis. Recently Pt/PPD/GOx sensors have also been used to study the effects of mild hypoxia and hyperoxia, neuronal activation (tail pinch), and anesthesia on brain ECF glucose.

Other recent work on ECF glucose monitoring using biosensors includes that of Hu and Wilson who used a needle-type biosensor (~100μm) to monitor changes in brain glucose in anesthetized rats. The sensor has a rigorous construction protocol involving Nafion®, cellulose acetate, bovine serum albumin, and polyurethane. It had a response time of about 5 s and its usefulness was demonstrated by examining the time-dependent interstitial glucose concentration in the rat hippocampus in response to KCl depolarization and by stimulation of glutamate neurons through the perforant pathway. Shram et al. have also reported the use of a glucose biosensor in the living brain. The sensor was constructed by immobilizing GOx onto the surface of a carbon fiber either by cross-linking with gluteraldehyde (the latter, in given conditions, was also covered with an additional membrane of Nafion® or cellulose acetate to eliminate proteins) or by enzyme entrapment in electropolymerized films of m-phenylenediamine. These glucose sensors were operated using DNPV and were reported to be insensitive to interfering substances such as AA. With properly chosen pulse parameters, the response to glucose resulted in a peak at a potential of about 1 V (versus Ag/AgCl) due to the oxidation of the enzymatically produced hydrogen peroxide. Extracellular brain concentrations were monitored in anesthetized rats during administration of insulin and glucagon. These sensors were later used in a detailed investigation of brain glucose in anesthetized rats under normal and hyperglycemic conditions.

One of the principal motivations of the above work to develop and utilize a reliable, selective and rapid response glucose biosensor in the living brain is the fact that glucose is the major source of energy for the mammalian brain under normal physiological conditions. However, over the past few years there has been increasing evidence that lactate, synthesized and released by astrocytes, may also serve as an important energy substrate for neurons in the adult brain. This prompted Hu and Wilson to construct a lactate biosensor by substituting lactate oxidase for GOx in their original biosensor design. The resultant sensor was used to monitor brain extracellular lactate in anesthetized animals and changes due to neuronal activity were examined in the dentate gyrus of the hippocampus after electrical stimulation of the perforant pathway. Shram and co-workers have also reported a lactate-specific biosensor based on a CFE coated with lactate oxidase. Operated with their previously reported DNPV method for glucose they performed preliminary in vivo experiments in the cortex of the anesthetized rat.

An interesting new approach to in vivo neurochemical monitoring that has also been applied to monitoring ECF lactate is the dialysis electrode reported by Albery and co-workers. This system combines the advantages of in vivo monitoring using voltammetry with those of microdialysis: working, reference and auxiliary electrodes are inserted into the tip of a microdialysis probe and the chosen enzyme introduced by slow perfusion using a microdialysis pump (as in a conventional microdialysis experiment). This arrangement achieves the good sensitivity, time resolution and continuous output of an implanted electrode, with the added advantage that fresh enzyme or mixtures of enzymes can be added. The dialysis electrode is now available commercially (Sycopel International Ltd., UK) and has been used by Ikegami et al. to monitor the concentration of extracellular lactate in the cerebral cortex of urethane-anesthetized rats. In addition to the lactate specific lactate oxidase, ascorbate oxidase was used to help eliminate AA interference.

7.8 Glutamate

L-Glutamic acid is a key excitatory amino acid neurotransmitter in the mammalian brain, and the measurement of ECF glutamate is a key step in elucidating its role in CNS physiological and pathological states. Although microdialysis collection with ex situ detection of glutamate has been widely used, the ability to
monitor continuous real-time glutamate dynamics has only recently been realized due to the availability of the newly isolated enzyme, glutamate oxidase (GLUOx), and the development of GLUOx-modified electrodes. Because the concentration of glutamate in brain ECF (about 3 μM\(^2.25\)) is much less than that for glucose, the problem of interference by reducing agents, especially AA, is more severe. Consequently, in comparison to ECF glucose, reports of brain glutamate monitoring with implanted biosensors have been more limited.

Wilson and co-workers have used glutamate sensitive microelectrodes to monitor changes in ECF glutamate in the brains of anesthetized rats.\(^{2.29}\) Constructed in a similar manner to their glucose biosensor,\(^{2.24,2.28}\) these devices also have underlying layers of both Nafion\(^\circledR\) and cellulose acetate to help eliminate interference problems. GLUOx and ascorbate oxidase were co-immobilized by droplet evaporation from a bovine serum albumin/glutaraldehyde solution. The sensor was operated at +600 mV (versus Ag/AgCl), had a rapid response time (about 1 s), and a high degree of sensitivity (<2 μM) and selectivity. Placement of the electrode in the dentate gyrus of the hippocampus led to the detection of both KCl-induced release of glutamate and release induced by electrical stimulation of the perforant pathway, despite a 50% decrease in sensitivity observed immediately following implantation in tissue.

A glutamate sensitive dialysis electrode (see section 7.7) has also been used for the continuous measurement of glutamate efflux in the brain of a freely moving rat following a 5-min tail pinch.\(^{2.21}\) A Nafion\(^\circledR\)-coated Pt working electrode was held at a potential of +650 mV (versus Ag/AgCl) and the enzymatic production of hydrogen peroxide by GLUOx entrapped within the dialysis membrane monitored. Electrochemical interference from AA was eliminated through the use of ascorbate oxidase. The response time in vivo of this sensor was of the order of 1 min. Several other groups have also used this type of biosensor to monitor brain glutamate. Walker and co-workers monitored both glutamate and AA in rat hippocampus after perforant path stimulation in a study of epileptic discharge after seizure.\(^{2.45}\) Asai et al. used a dialysis electrode to monitor extracellular glutamate in rat striatum and demonstrated two distinct phases of glutamate release during early severe brain ischemia.\(^{2.27}\)

The problem of oxygen interference under such conditions was assumed to be overcome by perfusion of the enzyme solution resulting in a stable oxygen supply at the reaction site on the electrode surface. Both latter studies were performed in acute preparations with response times of between 10–15 s. The Nafion\(^\circledR\) coating was replaced with a PPD layer to help further reduce interference.

More recently, a new glutamate biosensor has been reported that involves the simple entrapment of GLUOx on a platinum electrode surface (120 μm) with a PPD film, in a similar manner to that reported by Lowry et al.\(^{2.17,2.18}\) for glucose. A detailed characterization in vitro of this sensor has been performed indicating similar characteristics to the Pt/PPD/GOx sensor, and suggesting ideal suitability for monitoring in vivo.\(^{2.29}\) Preliminary experiments in vivo to detect extracellular glutamate in the awake, freely moving rat at 1 s intervals using a mild stressor (10-s tail pinch) have been reported for this device.\(^{2.29}\)

Another analyte on which some preliminary monitoring in the brain has been performed using enzyme-modified electrodes is choline. Michael and co-workers developed amperometric biosensors for peroxide, choline and acetylcholine by immobilizing horseradish peroxidase (HRP), choline oxidase (CHOx), and acetylcholinesterase in a cross-linked redox polymer deposited on glassy carbon electrodes.\(^{2.30}\) Co-immobilization of HRP and the model GOx was used to establish the feasibility of highly efficient bienzyme sensors at low substrate levels. Replacing GOx with CHOx produced sensors with submicromolar detection limits and a linear response up to 0.8 mM choline. Addition of acetylcholinesterase to the sensors generated a relatively small response to acetylcholine that demonstrated the feasibility of trienzyme sensors. Similarly prepared CHOx-electrodes based on 7 and 10-μm diameter CFEs have been used by the same group to monitor choline transients in vivo in the rat brain following local injection of choline near the electrode.\(^{2.30,2.32}\) The electrodes were operated at −0.1 V versus SCE and exhibited a decrease in sensitivity of less than 25% following 5 h of exposure to brain tissue. The response time of all these sensors was less than 30 s, with 2 s response times achieved in some cases.

8 COMPARISON WITH BRAIN MICRODIALYSIS

As an alternative to VIV for neurochemical analysis in intact tissue, in vivo microdialysis involves the perfusion of the tissue (using a permselective membrane), collection of the dialysate, and subsequent analysis following separation (usually by HPLC or capillary electrophoresis). Electrochemical detection is often used to quantify the concentration of species present in dialysates, although other forms of detection are available, such as spectroscopic and refractive index measurements. Recent reviews of microdialysis methodologies cover issues such as comparison with other sampling techniques,\(^{2.303}\) technological advances,\(^{2.304–2.306}\) critical analyses of the physiological significance of species in the dialysate,\(^{2.307–2.311}\) studies of peripheral physiology,\(^{2.312}\) pharmacokinetics,\(^{2.313–2.315}\)
calibration issues, biotechnology applications, behavioral studies, and applications in the human brain.

The microdialysis technique has been applied to humans in clinical studies, including head injury, ischemia, pharmacokinetics, glucose metabolism, neuromediator function, and for monitoring during brain surgery. The majority of these have been investigations of peripheral physiology, such as metabolite kinetics in skeletal muscle, histamine release in skin, and the effect of drugs and physical exercise on fat metabolism. The greater analytical certainty associated with cerebral microdialysis has also led to clinical applications in the brain. Of particular interest has been the role of excitatory amino acid neurotransmitters and dioxygen in the development of brain tissue damage following head injury. Neurochemical correlates of epileptic seizures have also been studied using the dialysis technique to quantify the involvement of glucose metabolism and neuromediators in this phenomenon.

An advantage of microdialysis is that a wide range of compounds – neuromediators, metabolites, amino acids, drugs, etc. – can be collected in each sample and separated reliably using recent advances in HPLC and electrophoretic technologies. The main disadvantages of dialysis at present are the relatively large probe size available (minimum about 200 µm) and the poor time resolution, ranging from 1–10 min. Voltammetry, on the other hand, has a more limited range of analytes, and often VIV studies are restricted to monitoring one analyte at a time. Its advantage of small probe size and high temporal resolution, however, allows investigations not possible with microdialysis.

Since their introduction in the early 1970s, in vivo voltammetric methods have provided researchers with a means of studying the dynamics of neurotransmitter release mechanisms in whole animals and brain slices, and more recently in single cells in culture. Using microelectrodes (5–30 µm OD, outside diameter), generally made of carbon, investigators have studied the signaling dynamics of neurotransmitters and neuromodulators such as dopamine (DA), norepinephrine (NE) and serotonin (5-HT), and more recently nitric oxide (NO) and glutamate. Unlike the complimentary technique known as microdialysis, in vivo voltammetric methods allow for the very rapid (1–200 Hz) and spatially resolved (5–30 by 30–150 µm as compared to 200–300 µm by 1–4 mm) measurement of the dynamic properties of neurochemicals. However, the routine detection limits of such methods are in the 25–50-nM range for analytes such as DA, 5-HT and NO, and these do not rival the picomolar detection limits of methods used to analyze microdialysis samples.

These seemingly straightforward methods have been plagued by methodological problems, primarily dealing with the selective and sensitive measurements of neurotransmitters. Microelectrodes and associated recording techniques must be able to measure and identify selectively the analytes of interest without the use of powerful separation and quantitation methods such as high-performance liquid chromatography coupled to electrochemical detection (HPLC/EC). Improvements in microelectrode technologies and recording methods have greatly enhanced the utility of such methods for a variety of studies.

The purpose of this chapter is to give readers a general introduction to in vivo voltammetric methods that can be applied to studies of neurotransmitter and neuromodulator signaling dynamics in brain tissues and in cells in culture. We discuss the types of microelectrodes that are now used to record neurochemicals as well as surface modifications that are carried out on these microelectrodes to make them more sensitive and selective for different neurochemicals. The different recording methods and some of their inherent strengths and weaknesses are reviewed as well as the instrumentation currently used to record from microelectrodes for such measures. Finally, we discuss some of the applications of these methods and how they compare with other in vivo recording methods such as microdialysis and fiber optic sensors. This review does not focus on the biological systems that have been studied with these methods and the results of such studies. The major purpose is to give the reader an overview of in vivo voltammetry methods and how they can be used to study neurotransmitter and neuromodulator signaling dynamics in biological systems. Future developments in this field hold great promise for developing a large number of new microelectrodes for detecting a variety of neurochemicals in order to gain an understanding of chemical signaling.
which is an integral part of central nervous system (CNS) biology and all biological systems.

1 INTRODUCTION

The concept of using in vivo voltammetric recordings for the analysis of neurotransmitters and neurochemicals, such as DA, in the CNS was pioneered by Ralph Adams in the early 1970s. The basic concept of the methodology is seemingly straightforward and is illustrated schematically in Figure 1. A voltammetric microelectrode is implanted in the brain region that contains the nerve endings, varicosities or dendrites of interest. More recently, this approach has been used in slices of brain tissue and in cell culture. Voltammetric recordings are carried out using a recording method with a sensitive potentiostat connected to the microelectrodes to measure the neurotransmitter of interest. Thus, the release of a neurotransmitter can be measured and related to the function of the CNS. Unfortunately, there are a number of methodological considerations that have needed refinement in order to carry out these seemingly simple measures reliably. In particular, the type of recording electrode and the choice of voltammetric recording method are critical for the rapid, sensitive, selective and reliable detection of certain neurotransmitters and neurochemicals.

During the 1990s, the techniques of FSCV, FCV and HSC were refined for rapid in vivo electrochemical measurement of neurotransmitters in brain slices and in the brains of mice, rats and monkeys. In contrast to microdialysis techniques, which permit measurement of basal extracellular levels and slow (ca. 1–20 min) changes in extracellular monoamines and metabolites, electrochemical recordings using 5–30-µm diameter microelectrodes allow for rapid (1–200 Hz) measurement of neurotransmitters and neuromodulators in discrete brain nuclei. In addition, such methods can dynamically monitor neurotransmitter release and clearance kinetics. Using rapid voltammetric recording methods our laboratory and others have measured DA, NE and 5-HT release and uptake. Improvements in recording methods have also allowed for the further identification of the detected neurotransmitter species, which has greatly increased the reliability of such measures. Moreover, numerous laboratories have been using amperometric recordings to measure release of neurotransmitters from individual cells in culture. Amperometric methods with modified microelectrodes have also been used to measure NO. Finally, future developments in microelectrode

Figure 1  Schematic diagram illustrating the basic instrumentation needed to perform in vivo voltammetric recordings. Waveforms 1, 2, and 3 show the input potentials and output waveforms for high-speed chronoamperometry (HSC), fast-scan cyclic voltammetry (FSCV), and fast cyclic voltammetry (FCV), respectively.
technologies hold promise for routinely measuring other neurotransmitters and neurochemicals such as glutamate, lactate, glucose and γ-aminobutyric acid (GABA).\(^{35-41}\)

This article is intended for those who want to gain a general knowledge of the principles, materials and techniques that underlie the current methodologies that are used to study CNS tissues and cells in culture using voltammetric methods coupled with microelectrodes. The current technologies that are used to measure neurotransmitters and neuromodulators, such as DA, NE, 5-HT, NO, glutamate and other neurochemicals, will be reviewed. We have endeavored to include mostly current data and references, but we have not tried to be comprehensive in our citation of all literature pertaining to this topic. There are additional reviews and review chapters that are recommended for those interested in the use of these methods.\(^{2,12,25,42}\) We have undoubtedly omitted some important information, but we hope that this article will be of value to numerous scientists who want to use these methods to study the dynamics of neurotransmitters and neurochemicals in biological systems.

### 2 ELECTRODES

As seen in Figure 1, the major tools that are used to carry out voltammetric recordings are microelectrodes that are implanted into CNS tissue or, in the case of single cell recordings, placed very close to the cells. The recording or working electrode is the electrode where the detection of the neurotransmitters or neurochemicals occurs. This is perhaps the single most important component of the recording system. A variety of different types of microelectrode, ranging in size from 5 to 200 µm in diameter, are used for such studies (see below). Reference and auxiliary electrodes are needed to carry out the measures without a drift in the potential that is applied to the working electrode.\(^{43}\) A basic understanding of electrochemistry at solid electrodes can be obtained from Bard and Faulkner\(^{43}\) or Adams.\(^{44}\) Basically, as a function of the voltammetric method and the magnitude of the potentials applied to the electrode surface (see section 3), electrochemical reactions occur at the surface of the microelectrode. The basic oxidation reaction for DA is depicted in Scheme 1.

DA can be oxidized to form an o-quinone that under certain circumstances can be reduced back to DA. The reaction is a two-electron process. The oxidation reaction for 5-HT is rather different and again involves a two-electron reaction as seen in Scheme 2.

These reactions can occur at the surface of the working electrodes provided the voltammetric method (section 3) produces potentials at the microelectrode surface that are sufficiently large to cause the oxidation of these compounds and if the analyte is adjacent to the surface of the microelectrode. The current flow caused by these chemical reactions or faradaic current is proportional to the concentration of the analyte. While one equation cannot be used to describe the current response of all voltammetric recordings as they are related to the recording method (see section 3 and Bard and Faulkner\(^{43}\)), the basic response of a large electrode at potentials > 100 mV beyond the oxidation potential for a given analyte can be described in Equation (1)

\[
i = nFAC_bM
\]  

where \(i\) is the current measured, \(n\) is the number of electrons for a given chemical reaction, \(F\) is the Faraday constant, \(A\) is the total active recording surface area of the electrode, \(C_b\) is the bulk solution concentration of the analyte and \(M\) is a general purpose term encompassing mass transport of analyte to the electrode surface. In contrast to large electrodes, microelectrodes have both linear and spherical diffusion of analyte to the microelectrode tip and thus, if the response of the electrode is described accurately, an additional set of terms must be applied to model the electrode response completely.\(^{45}\) However, to understand the basic concepts of the measurements, the current recorded is directly proportional to the concentration of the analyte or neurotransmitter (\(C_b\)), the active recording area of the probe (\(A\)), the number of electrons per molecule (\(n\)) and the mass transport of the analyte to the surface of the microelectrode. In an unstimulated solution such as the extracellular space of the brain or in a quiet
solution next to a cell, a substitution can be made to Equation (1) to give Equation (2)

\[ i = XC_b \]  

(2)

where \( X \), the calibration factor for a given microelectrode, can be determined pre- and/or postexperimentation by varying \( C_b \) and measuring \( i \) under solution conditions that mimic the extracellular space of the brain (artificial cerebrospinal fluid) or the media in which cells are studied. Thus, a hallmark of many voltammetric recording methods is that the electrodes respond linearly to changes in concentration of the analyte. This forms the analytical foundation for the use of these methods in biological systems.

Using the aforementioned terms, the \( i \) recorded from oxidation or reduction of an analyte, such as DA, is more accurately depicted for chronoamperometry (CA) using a modified form of the Cottrell equation seen in Equation (3)\(^{4,45}\)

\[ i = \frac{nFAC_bD^{1/2}}{\pi^{1/2}t^{1/2}} + 4nFrrC_bD \]  

(3)

where \( t \) is the time of the measurement of \( i \) in seconds, \( D \) is the diffusion coefficient of the analyte, and \( r \) is the radius of the microelectrode.

The selectivity of recordings for the measurement of neurotransmitters such as DA in biological systems is a major issue. Modifications to microelectrode surfaces (see section 7) and the use of different recording methods (see section 3) have enhanced the selectivity of the voltammetric methods. In addition, selection of applied potentials can minimize interferents. However, voltammetric methods are inherently selective, as very few molecules in the extracellular space of the brain can be caused to oxidize or reduce. This is both an inherent strength and weakness of these methods. Although not comprehensive, Table 1 summarizes some endogenous and exogenous compounds that can be measured using voltammetric recording techniques using low or high oxidation potentials\(^{4,46,47}\). We urge caution because the actual oxidation potentials of these compounds are dependent on the recording electrode used, the recording method and any modifications of the microelectrode surface.

There are a variety of working, reference and auxiliary electrodes that are used to record neurotransmitters and neurochemicals. In the following sections we have tried to describe the basic compositions of the different electrodes and the advantages of each type.

### 2.1 Working Electrodes

The working or recording electrode used for in vivo voltammetric measurements in CNS tissues is generally fabricated to achieve a tip diameter of 5–200 µm, depending on the application. There are a number of types, and the choice of the size and type is often based on the molecule that will be measured and the recording preparation.

#### 2.1.1 Carbon Paste

Carbon paste electrodes are one of the oldest forms of electrodes used for in vivo electrochemical recordings in CNS tissues. They are formed by packing carbon paste into the end of a Teflon\textsuperscript{®} coated wire\(^{48}\) or by using a mixture of carbon epoxy that is packed into a glass capillary\(^{45}\). Carbon paste is prepared by mixing powdered graphite with a hydrophobic material such as liquid paraffin, silicone oil, or wax. Stearic acid is sometimes added to the paste to improve the electrode’s recording properties\(^{48}\). Graphite pastes can be mixed

| Table 1 Endogenous electroactive compounds and exogenous drug compounds that are electroactive, which are encountered in neurochemical studies\(^{46,47}\) |
|---------------------------------|------------------|
| Easy to oxidize                  | Harder to oxidize |
| DA                              | Melatonin        |
| NE                              | Metanephrine     |
| 5-HT                            | Normetanephrine  |
| Epinephrine                     | MHPG             |
| DOPAC                           | 5-HTP            |
| 1-DOPA                          | Tyramine         |
| AA                              | Octopamine       |
| 5-HIAA                          | Tryptamine       |
| Uric acid                       | Tyrosine         |
| DHPG                            | Tryptophan       |
| Catecholamine-related drugs     |                  |
| α-Methyl dopa                   |                  |
| α-Methyl DA                     |                  |
| α-Methyl NE                     |                  |
| Noradrenaline                   |                  |
| Carbidopa                       |                  |
| Other Drugs                     |                  |
| Acetaminophen                   |                  |
| β-Blockers                      |                  |

\(^{a}\) Compounds in bold are of most interest.

DOPAC, 3,4-dihydroxyphenylacetic acid; DOPA, 3-(3,4-dihydroxyphenyl)alanine; AA, ascorbic acid; 5-HIAA, 5-hydroxyindoleacetic acid; DHPG, 3,4-dihydroxyphenylglycol; MHPG, 3-methoxy-4-hydroxyphenylglycol; 5-HTP, 5-hydroxytryptophan; 3-MT, 3-methoxytryramine; HVA, homovanillic acid; MAO, monoamine oxidase.
with epoxy to form a graphite–epoxy mixture or used as they are to make the Teflon® wire-type electrodes. A commercially available graphite–epoxy mixture is used for some types of graphite–epoxy electrodes (PX-grade Graphpoxy, Dylon, Industries, Cleveland, OH). The resulting electrodes have tip diameters of 100–250 µm, depending on the resulting diameter of the graphite–epoxy filled glass capillary or the diameter of the Teflon®-coated wire. While useful for certain applications, the size of these electrodes precludes their use for many applications.

2.1.2 Carbon Fiber Electrodes

Working electrodes made from carbon fiber or carbon monofilaments are the most common and widely used forms of electrodes for CNS recordings. Basically, all of these electrodes are generally made by sealing one or more carbon fibers or carbon monofilaments in glass capillaries. For certain single cell recordings, the fiber is sealed in plastic pipette tips. Appropriate electrical connections to the fibers are made using silver pastes, graphite pastes or salt solutions.

There are numerous manufacturers of carbon fiber or carbon monofilament materials that range in size from 5 to 30 µm in diameter. Typical manufacturers and part numbers for popular fibers and one monofilament are as follows: 10-µm diameter (P-55, Amoco, Greenville, SC), 7–8-µm diameter (type HM or XA-S, unsized, Courtauld), 8–12-µm diameter (SOFICAR, Paris France), 30-µm carbon monofilament (#80036-001, Textron Systems Division, Wilmington, MA). In addition, a number of companies sell prefabricated carbon fiber-based electrodes. Some of these are Quanteon, LLC (Lexington, KY), World Precision Instruments (Sarasota, FL), Dagan Corp. (Minneapolis, MN), ALA Scientific (New York, NY), MPB Electodes (London, UK) and Axon Instruments (Foster City, CA).

Although often similar in size, the recording properties of different fibers can be quite different. This is attributed to the type of fiber and the methods and/or cleaning steps used to prepare the fibers. The degree of oxygen on the surface of the carbon will affect the recording properties of the fibers. It is a good idea to use carbon fibers and carbon monofilaments that have been previously characterized. As stated, the fabrication steps are quite similar for different carbon fiber electrodes (CFEs); however, the choices of glass, connecting wire, cements and other materials can be quite diverse. Typical fabrication methods for a variety of fiber electrodes are given by various authors.

One type of carbon monofilament-based electrode used for studies in our laboratory is constructed by cementing single “as pyrolyzed” 30-µm diameter single carbon monofilaments (#80036-001; Textron Systems Division, Wilmington, MA) inside a pulled glass capillary. A single glass capillary with a tip diameter of approximately 5 µm is pulled from a 2-cm length of (4.0-mm OD, 2.6-mm ID (inside diameter)) borosilicate glass tubing (Glass Warehouse, #26005) using a Narishige PE-2 puller. The tip of the pulled glass capillary is bumped to an inner diameter of 40–45 µm. A single carbon fiber (5 cm in length) is then passed completely through so that the fiber extends well beyond the tubing at both ends. A small drop of Epoxylite™ (The Epoxylite™ Corp., Westerville, OH) is placed on the carbon fiber at the exposed end of the glass capillary, and the fiber is then pulled into the tubing so that it is sealed well in the tubing with no excess Epoxylite™ on the exposed carbon fiber. This carbon fiber/glass capillary assembly is cured overnight in an oven set at 100 °C to dry the Epoxylite™. The open end of the larger tubing is then packed with a graphite–epoxy mixture (Graphpoxy™, Dylon Industries, Berea, OH) by smearing a layer of Graphpoxy™ on a microscope slide and tapping the back end of the electrode repeatedly through the Graphpoxy™ to the glass slide. It is generally not possible to fill the entire void with Graphpoxy™, but it is possible to see at least 3–4 mm of packed material through the side of the larger tubing. The tapping procedure results in breaking off the back end of the graphite fiber flush with the end of the larger tubing. The excess glass is cut off, exposing a glass capillary filled with Graphpoxy™ with a maximum OD of 500–750 µm. A 10-cm length of 36-gauge lacquer-coated copper wire is prepared by scraping 5 mm of coating from one end of the wire. The wire is then inserted into the back end of the larger tubing, through the Graphpoxy™. This results in a good electrical connection between the carbon fiber and the copper wire. Finally, a small drop of Epoxylite™ is placed on the copper wire at the point of attachment to the larger piece of glass tubing and the microelectrode is again baked overnight at 100 °C to cure the Graphpoxy™.

Once sealed in glass, the carbon monofilament or CFEs can be configured for a variety of applications. They are either cut and sometimes polished to form an oval disk electrode or trimmed to form a short cylinder (30–150 µm in length), which is perhaps the most popular form of CFE. A scanning electron micrograph of the tip of a 30-µm diameter cylindrical tip carbon monofilament electrode is shown in Figure 2. In addition to the extended cylinder, the tips of the electrodes can be etched or the electrodes can be electrically pretreated to enhance their recording properties.

2.1.3 Carbon Arrays

A novel type of array electrode that holds promise for future applications is manufactured using semiconductor
fabrication techniques on substrates of silicon. The potential advantages of array electrodes include: (1) reproducible recording sites, (2) the ability to record from multiple brain sites from a single probe, (3) spatially defined recording sites for recording from layered brain structures, (4) the ability to stimulate and record single unit or chemical activity electrically from the same recording sites, and (5) reduced cost compared to handmade electrodes. These electrodes have been characterized\(^{58}\) and used in vivo.\(^{59}\) Briefly, these electrodes are fabricated using photolithography to pattern recording sites, connecting lines and bonding pads on to an insulated silicon surface. The metalized connecting lines are insulated and then the recording sites are sputter-coated with carbon. At present, the recording characteristics of the carbon-sputtered multisite probes are worse than single carbon fiber microelectrodes.\(^{58,59}\)

2.1.4 Noble Metals

Platinum (Pt) or platinum–iridium (Pt–Ir) wires, often sealed in glass, form the foundation of a number of electrodes that are being developed to measure other neurotransmitters and neurochemicals by using oxidative enzymes attached to electrode surfaces.\(^{35–41,60,61}\) These microelectrodes can be made ranging from 5 to 250 µm in diameter. In general, Pt and Pt–Ir are not ideal surfaces for measuring molecules like DA, NE and 5-HT. However, they are excellent for measuring peroxide formed from oxidative enzymes or enzyme cascades. A particularly unique type of recording electrode has been developed that is actually a combination of a microdialysis probe and a platinum electrode and has a 230-µm OD. These electrodes are called dialysis electrodes and they are sold by SyCopel International Ltd (Tyne and Wear, UK).\(^{62}\) They are very versatile, as they can be filled with a variety of oxidative enzymes to make them sensitive to a number of analytes, such as glutamate and lactate.

2.2 Reference and Auxiliary Electrodes

A stable reference is an important element of the electrochemical measurement because the potential of the working or recording electrode is changed relative to a stable reference electrode. By contrast, many laboratories do not use an auxiliary electrode, because of the small currents and low impedance of the recording solutions. However, some instruments still work in a three-electrode (auxiliary, reference, working) versus two-electrode (reference, working) mode. Generally miniature forms of reference electrodes and auxiliary electrodes are used so that they can be directly implanted into CNS tissue. However, for brain slice and single cell recordings, standard size reference electrodes are often employed.

2.2.1 Ag/AgCl Reference Electrodes

The miniature Ag/AgCl electrode is the most common reference electrode used for voltammetric recordings in CNS tissues.\(^{4,6,10,15,20}\) These can be made by using a short length (4–6 cm) of Teflon\(^{*}\)-coated (250-µm OD) silver wire. The Teflon\(^{*}\) is removed from 3–5 mm on one end. A voltage of +0.5–+1 V is applied to the Ag wire that is submerged in 1-M HCl for about 5–10 min using a platinum wire as the cathode. The Ag/AgCl reference should be a silver gray color. A standard size Ag/AgCl reference that is used for slice and single cell recordings is the RE-5 (BAS, Bioanalytical Systems, Lafayette, IN).

2.2.2 Hg/HgCl\(_2\) Sodium Saturated Calomel Electrodes

The sodium saturated calomel electrode (SSCE) is a less popular reference, but it is still used.\(^{12}\) Mercury is in contact with a solution that is saturated with mercury(I) chloride and NaCl. These can be made in-house or purchased from private manufacturers.

2.2.3 Auxiliary Electrodes

As previously stated, auxiliary electrodes are not always used for voltammetric recordings with microelectrodes. A standard auxiliary electrode is a Teflon\(^{*}\)-coated silver wire (250-µm diameter) that has 3–5 mm of the Teflon\(^{*}\) removed from one end. This is placed in contact with brain tissue or cell supernatant, or for whole animal recordings the Ag wire is connected to the skull via a screw that is in contact with the dura. Alternatively, a stainless steel wire in contact with CNS tissue or the perfusion medium is used.\(^{24}\)

3 RECORDING METHODS

The choice of recording method is perhaps the single most confusing aspect of voltammetric recordings in CNS...
tissues and cells. In this section we have tried to explain the different recording methods and how they have been used to study neurotransmitters and neurochemicals in CNS tissues and single cells. The methods are all based on the way the potential is varied at the working electrode to record the oxidation or reduction of analytes, such as DA. Basically, as depicted in the inset to Figure 1, recording methods usually involve applying voltages to the working electrodes using square waveforms, triangle waveforms or a combination of triangles and squares. In addition, the voltage can be constantly applied for certain applications. The choice of the recording method for a given study will depend on the temporal resolution, potential confounding substances, the size of the electrode needed and the sensitivity required for the measurements. In addition, the availability of instrumentation to perform the different methods and personal preferences must also be considered.

3.1 Amperometry

Amperometry involves the measurement of current at a constant fixed potential and is the simplest of the electrochemical techniques. The current can be monitored continuously for this technique has the ability to record events that occur very fast (200–1000 Hz). In addition, since the voltage is applied to the working electrode constantly, the nonfaradaic background current recorded from the electrode is very low, allowing for very sensitive measurements. Amperometry is used with HPLC/EC systems, which accounts, in part, for the high sensitivity of these methods. Amperometric recordings, because of the high sampling resolution, are used to study catecholamines released from single cells. In addition, amperometry is useful for measuring compounds such as hydrogen peroxide, NO, and ascorbate. Hydrogen peroxide is of interest because it is the product of oxidase enzymes such as glutamate oxidase. Enzyme modified electrodes will be discussed later.

The danger of fixing the potential is that analytes and analyte oxidation products readily adhere to the electrode. This poisoning of the electrode changes its recording properties. Also, when using a fixed potential the source of the analytical signal cannot be determined because any species that is electroactive at the potential applied to the working electrode will contribute to the current (see Table 1). Cahill and Wightman overcame this problem by the use of two electrodes to differentiate between ascorbate and catecholamines. The first electrochemically modified carbon fiber potential was set at +0.05 V versus SSCE. This electrode was selective for ascorbate. A second unmodified CFE was set at +0.65 V and detected ascorbate and catecholamines. Currents obtained from both electrodes were used to determine the species being released from bovine adrenal medullary cells. Thus, a combination of electrodes can be used to overcome some of the limitations of amperometry. However, in general, amperometric recordings are used to study very rapid (<1 s) release of catecholamines from single cells and to carry out studies of NO and measures involving oxidase enzyme-based electrodes in CNS tissues.

3.2 Chronoamperometry

CA is one of the oldest methods used for in vivo electrochemical measurements in CNS tissue and is based on the work of Cottrell, as discussed by Bard and Faulkner. An applied potential is instantaneously stepped from a resting value to a higher potential that is usually 50–100 mV in excess of the oxidation potential of an analyte. The potential is held at this higher value for ca. 1 s then it is stepped back to the resting potential. Current is measured after the potential has been stepped, during the time that the nonfaradaic background current of the electrode has declined (ca. 100 ms). Current increases dramatically as the potential is stepped from its resting value. This is caused by the charging current of the electrode and the electroactive species that is being oxidized. The charging current decays with time as the potential is held at its higher value (see Waveform I in Figure 1). An advantage of this method is that the current recorded from the analyte is directly proportional to the concentration of the analyte and therefore the current can be summed or averaged over most of the measurement, once the charging current has declined for ca. 5–20 ms. Another advantage of this method is that the background charging current of the electrode is a minor component of the signal, which enhances the signal-to-noise of the recording method. These square wave potential steps have been repeated at 60-s intervals to monitor events that occur as a function of time using stearate-modified carbon paste electrodes. Typical resting and applied potentials were −0.15 V and +0.25 V versus Ag/AgCl reference, respectively when using stearate-modified carbon paste electrodes to measure extracellular DA.

3.2.1 High-speed Chronoamperometry

High-speed chronoamperometric recordings are a rapid version of the aforementioned methods originally described by Cottrell. They have been used to measure DA, NE, 5-HT and NO in a variety of preparations. These methods are advantageous because they are rapid, sensitive and record data that can be used further to identify the detected compound(s).

A carbon fiber microelectrode is held at a resting potential of −0.20–0.0 V versus Ag/AgCl reference; electrochemical recordings are made in a suitable buffer...
solution to simulate CNS tissue. The voltage is then instantaneously stepped to an oxidation voltage of +0.45 to +0.55 V. This voltage step is chosen to exceed the oxidation potential of the potential analyte, in this case the biogenic amine neurotransmitters such as DA and 5-HT, by at least +0.10 V. This produces a rapid change in the current recorded by the microelectrode that rapidly decays as a function of time. This charging current is allowed to decay for 4–20 ms before the background current of the microelectrode is measured. The square-wave voltage step is held at the oxidation voltage for a fixed time period of 20, 50 or 100 ms, during which the oxidation current is sampled for 15, 40 or 80 ms. The square-wave voltage step is then instantaneously returned to the resting potential. Similar to the case of the first oxidation step, the return of the potential to the resting voltage produces a reduction reaction at the surface of the electrode. A rapid decrease in the reduction current represents the charging current of the recording and this is allowed to decay for 4–20 ms. The resting voltage is maintained for a fixed period that is identical to the prior square-wave step of 20, 50 or 100 ms. Like the oxidation current step, the current is sampled for a fixed time period of 15, 40 or 80 ms. In our studies, a 50-kHz sampling rate is employed to measure the oxidation and reduction current portions of the signals. As the current is integrated, the correct term for this type of recording is high-speed chronocoulometry.\(^{(58)}\) The symmetric voltage steps are continued at a set time period to produce signals with a sampling resolution of 5 Hz (100-ms oxidation, 100-ms reduction; 5 per second), 10 Hz (50-ms oxidation, 50-ms reduction; 10 per second) or 25 Hz (20-ms oxidation, 20-ms reduction; 25 per second). In theory, the signal-to-noise ratio of such recordings is greatly enhanced because small changes in current due to the detection of an analyte are not masked by large background current. In addition, potential changes in the background current of an electrode that do not relate to increases or decreases in an analyte are potentially less prone to produce recording artifacts, owing to the lower background current levels. Typical detection limits for DA and 5-HT are 25 nmol using a 30-µm diameter carbon cylinder electrode.\(^{(68–70)}\)

In a similar way to FSCV methods (see below), HSC recordings yield information regarding the major contributor to the electrochemical signal.\(^{(58,68–70)}\) The detection of DA yields reduction to oxidation (red/ox) current ratios with Nafion\(^{TM}\)-coated electrodes between 0.5 and 0.9 depending on the thickness of the Nafion\(^{TM}\) film and the drying temperature of the Nafion\(^{TM}\)-coating procedure.\(^{(68,10,68–70)}\) In contrast, AA produces red/ox ratios of 0.0 and 5-HT produces ratios of 0.0 to 0.2.\(^{(8,15,16,68–70)}\) Thus, somewhat analogous to the waveforms seen with FSCV (see below),\(^{(7,12)}\) DA, AA and 5-HT produce distinctive red/ox ratios which can be used further to identify the detection of these compounds in brain tissue.

Many recordings in CNS tissues and other applications do not require temporal resolutions of 5–25 Hz. Therefore, for more standard recordings, the signals are averaged over a 1- or 2-s time period.\(^{(68–70)}\) This further enhances the signal-to-noise ratio of the recording methods and decreases the number of data points that must be stored by a microcomputer recording system.

### 3.2.2 Double Potential Step

Double potential step CA or differential pulse amperometry (DPA) involves stepping the potential from a resting potential to a higher potential that oxidizes easily oxidizable, interfering species such as ascorbate. The current measured at this time is a result of the background current and any easily oxidized interfering species. The potential is again stepped to the final potential. The current measured at this point is caused by the background, interfering species and analyte. The difference in current between the prepotential and final potentials is recorded. In this way, the contribution due to the background and interfering species can be minimized. The main drawback of DPA is the lower temporal resolution compared to FCV or HSC (scan rate = 1 Hz). Using DPA, DA can be measured with untreated CFES using a resting potential of −240 mV and a final potential of +200 mV. The measuring pulse duration was 400 ms with a measuring pulse amplitude and prepulse duration of 50 mV and 100 ms, respectively.\(^{(17,70)}\) The electrodes were 50 times more sensitive to DA than AA and the detection limit was 0.5 µM. Electrochemical pretreatment of the electrodes was seen to lower the detection limit to 5 nM at the expense of a great decrease in response time (10–30 s).

### 3.3 Cyclic Voltammetry

In cyclic voltammetry (CV) the current is measured as the potential is steadily ramped up from a starting potential to the switching potential where it is ramped down to the starting potential (see the triangle wave 2 in Figure 1). The scan rate is typically between 10 and 300 mV s\(^{-1}\). CV is classically used as a qualitative technique for determining red/ox potentials and diffusion coefficients of molecules. Typically the starting potential is lower than the oxidation potential of the analyte of interest (ca. −0.5–0.0 V). In an unstirred solution, as the potential becomes more positive the recorded current becomes more negative as the electroactive species begins to be oxidized. If the electrode is large enough a peak will be seen at the oxidation potential due to depletion of the electroactive species near the electrode surface. If the electrode is small, a plateau will be seen because spherical
diffusion will be sufficient to bring fresh molecules to the electrode surface to be oxidized. After the potential ramp is reversed, the current begins to rise as the oxidized species that has not diffused away from the electrode begins to be reduced. If the electrode is sufficiently small, no reduction peak will be seen because all of the reduced species will have diffused away from the electrode surface. While used as a tool to characterize working electrodes, normal CV is rarely used for in vivo electrochemical recordings due to its slow recording rates. For a complete discussion of CV refer to Bard and Faulkner.\(^{(143)}\)

### 3.3.1 Fast-scan Cyclic Voltammetry (Triangular)

FSCV uses the same triangular-shaped ramps in potential as normal CV but at very high scan rates. This is one of the most popular in vivo voltammetric methods due to its excellent sensitivity, time resolution and compound identification capabilities.\(^{3,7,12,14,16}\) Typical resting and switching potentials are \(-0.4\) and \(+1.0\) V, respectively, for DA. With FSCV, much higher scan rates are used compared with CV (300–900 V s\(^{-1}\)). The high scan rates are coupled to 10-Hz repetition rates to track rapid biological events. However, high scan rates cause large background currents, which can increase the limit of detection (LOD). To obtain an analytically useful signal, the voltammograms are background-subtracted to make the analyte peaks (faradaic current) apparent. A background voltammogram or series of voltammograms is selected and subtracted from subsequent scans during a recording session.

Repetitive CVs, often 10 Hz, are sampled to obtain time-dependent concentration profiles. The current is averaged over a desired potential range corresponding to oxidation (or reduction) of the analyte. The interval between successive scans is at least 5–10 times the duration of each individual scan to allow the diffusion layer to return to its prescan state. Typically analytes are sampled up to approximately 8 \(\mu\)m from the electrode surface.\(^{12}\)

The voltage ranges of the oxidation and reduction peaks on the voltammograms or the shapes of the voltammograms can be used to identify compounds that are responsible for a given signal. As with HSC, the ratio of the oxidation and reduction peaks can be used to help identify the analyte. In addition the number of peaks can be used to identify the source of the sensor response. Although their oxidation peaks were overlapping (+0.53 V), DA was distinguished from 5-HT because DA had a single reduction peak at \(-0.18\) V but 5-HT had two reduction peaks at \(-0.05\) and \(-0.56\) V. A dual wave triangular potential was used with resting and switching potentials of \(-0.7\) and \(+1.3\) V, respectively. The scan rate was 813 V s\(^{-1}\) and the triangular waveform was repeated at 4 Hz.\(^{(71,72)}\) In another recent report, three-dimensional plots of voltage versus time with current plotted in false color were used to visualize the source of the sensor response. This was useful for distinguishing between DA, 5-HT, and pH changes during FSCV recordings.\(^{(73)}\)

Measurements of DA using FSCV have been shown to be dependent upon divalent cation concentrations such as \(\text{Ca}^{2+}\) and \(\text{Mg}^{2+}\) and changes in pH.\(^{(12,74)}\) Also, the oxidation of DA with double potential step CA and CV yields higher currents than would be expected from a species that was free to diffuse away from the electrode following oxidation.\(^{(75)}\) These studies support the hypothesis that oxidation of DA at CFEs involves significant adsorption of the analyte. Unlike FSCV, HSC does not seem to be affected by changes in divalent cations and no effects from pH changes have been reported.\(^{(8,68–70)}\)

DA has been most extensively measured using FSCV. In addition NE and 5-HT have been quantified.\(^{(3,12,14,16,76)}\) Recordings for NE are inherently less sensitive than those for DA.\(^{(12)}\) Also NE gives a similar waveform signature to DA. 5-HT is readily discerned from NE, DA and other neurochemicals. In contrast to DA where the scan rate was 300 V s\(^{-1}\) and the resting and switching potentials were \(-0.4\) and \(1.0\) V, respectively, the potential was scanned from 0.2 to \(1.0\) to \(-0.1\) to \(0.2\) V with a scan rate of 1000 mV s\(^{-1}\).\(^{(3,76)}\) By using this alternate waveform and scan rate the follow-up reaction where surface adsorption occurs was minimized. Nafion\textsuperscript{TM}-coated electrodes were 20 times more sensitive to 5-HT than DA. Typical detection limits for DA and 5-HT are 25–50 nM with these methods. Finally, histamine and oxygen can be quantified using FSCV.\(^{(12,77)}\)

### 3.3.2 Fast Cyclic Voltammetry (1 \(\frac{1}{2}\) Triangle)

Another approach involving CV recordings uses a triphasic ramp voltage as the waveform (see Waveform 3 in Figure 1).\(^{(20,22–24,78)}\) This technique has been called \(1 \\frac{1}{2}\) triangle or FCV. With this “W”-shaped waveform the potential decreases from the resting potential to a lower potential. The potential then increases to the switching potential, which is higher than the resting potential. The potential is finally ramped down to the lower potential then back to the resting potential. Each scan typically lasts 15–20 ms and the scan rate is 300 V s\(^{-1}\) or higher. The frequency of scans is usually 1 Hz. The resting, lower, and upper potentials are 0, \(-1\), and \(+1\) V, respectively. Using this approach, DA has an oxidation peak at \(+0.6\) V and a reduction peak at \(-0.2\) V at certain carbon fiber microelectrodes.\(^{(79)}\) With this waveform the detection limit of such electrodes has been reported to be about 200 nM. Increased sensitivity for DA has been shown when the upper potential was increased to \(+1.4\) V, which was attributed to increased analyte adsorption and activation of the carbon surface.\(^{(80)}\)
3.3.3 Sine-wave Cyclic Voltammetry
Another CV method involves the use of sine wave driving voltages. Sine wave-based CV techniques are those that involve using a nonlinear scanning input voltage instead of the linear ramps and pulses used in other techniques. The slopes of the voltage ramps are constantly changing and the potential is essentially held at the switching potentials instead of being rapidly switched. The first example is continuous scan cyclic voltammetry (CSCV). CSCV was developed to increase the temporal resolution of voltammetry. The input voltage was a 100-Hz sine wave with a peak potential of +1.0 V and a minimum potential of −0.5 V. Background subtraction was again used and the current was sampled every 10 ms. An advantage of CSCV over FCV is that fast scan rates can be used without losing sensitivity. Sample and hold circuits were used and set at +0.59 and −0.27 V for measuring DA. Some microelectrodes were able to detect DA with a detection limit of 10 nM. Interestingly, investigators have not taken advantage of the AC signal properties of these recordings to increase sensitivity or to further identify analytes.

The second example involves a triphasic sine wave like that used with FCV. The triphasic sine wave (2 Hz) was used to overcome the artifact seen when the polarity of a linear potential ramp is switched. The resting, upper and lower potentials were 0, −1, and +1.3 V, respectively. The potential followed a sinusoidal wave down to the lower potential where it climbed to the upper potential. The sine wave went to the lower potential then back to resting potential. DA yielded single oxidation (+0.6 V) and reduction peaks while NO showed a single oxidation (+1.2 V) and two reduction peaks. DA and NO were quantified simultaneously by following the current at different potentials when using high scan rates with the triangle waveforms.

3.4 Linear Sweep Voltammetry
In linear sweep voltammetry (LSV) current is measured while the voltage is steadily ramped, usually at slow rates of 10–20 mV s⁻¹. Using some electrodes, a peak is observed for an electroactive species in unstirred solutions caused by depletion of the species near the electrode. The electroactive species is only partially replenished by diffusion. The linear sweep is applied at regular intervals (ca. 5–10 min) and is not a fast recording technique. A semiderivative circuit is used to improve the resolution between peaks for LSV. Although LSV and semiderivative LSV have been used to track in vivo changes in neurotransmitters, the speed of the technique limits its utility for many applications.

3.5 Rotating Disk Recordings
Rotating disk electrode voltammetry (RDEV) has been applied to measuring uptake and release of neurotransmitters, such as DA and NE, in brain tissue minces and cells in culture. RDEV is unique because larger glassy carbon electrodes (3 mm) are used and the electrode actually stirs the sample solution. A constant potential is applied to the electrode which is usually >100 mV past the peak oxidation potential of the analyte of interest. The analyte is brought to the working electrode surface by a constant stirring motion produced by spinning the electrode at a constant rate. The Levich equation can be used to describe the response of the electrode. These techniques have been applied to studying the kinetics of neurotransmitter uptake in tissue pieces and cell suspensions.

Using these methods, DA was measured as the limiting current recorded at a glassy carbon RDE (rotating disk electrode) at an applied potential of +0.45 V versus Ag/AgCl reference. The rotation was 2000 rpm. Both NE and DA have been measured in cell suspensions using RDEV. In another study, a two-electrode system was employed to measure two analytes. DA and m-tyramine transport in cell suspensions was investigated using two RDEs. The potential of the first electrode was held at +0.4 V versus Ag/AgCl reference. Current measurements at this electrode corresponded to the oxidation of DA alone. The second electrode’s potential was set at +0.65 V to measure both DA and m-tyramine, with both electrodes rotating at 4000 rpm.

3.6 Differential Pulse Voltammetry
In differential pulse voltammetry (DPV), there is a linear ramp in potential with superimposed steps in potential that happen at regular intervals. The current is measured for short time periods before and at the end of each pulse. The difference between these is plotted versus potential to yield voltammograms with pronounced peak shapes. The power of this technique is in resolving between compounds with similar oxidation potentials. The drawback of DPV is the temporal resolution: about one scan per minute.

DPV has been used to measure DOPAC in both the nucleus accumbens and striatum in the rat CNS with two electrically pretreated pyrolytic 12-μm CFES. One scan was completed every 5 min, as the potential range was −0.2 to +0.35 V with a scan rate of 5 mV s⁻¹. The pulse amplitude was 50 mV with a frequency of 2 Hz. Individual oxidation peaks were observed for AA, catecholamines, indolamines, and uric acid. The separation of different
compounds is a clear advantage of this methodology. However, its slow sampling rate precludes the use of DPV for many applications.

3.7 Differential Normal Pulse Voltammetry

Differential normal pulse voltammetry (DNPV) involves stepping the potential from a resting potential to a higher potential then stepping the potential to a slightly higher potential. The potential is returned to the resting potential and the previous potential steps are repeated while sequentially increasing the step size. The difference between the prepulse and final potential values is recorded. The advantage of this technique over DPV is that the potential returns to the resting potential between measurements. DNPV has been used to measure DOPAC. A scan was completed every 2 min from −0.26 to +0.16 V versus Ag/AgCl reference. The scan rate was 3−4 mV/0.4 ms with a prepulse duration of 70−80 ms. The pulse duration was 40 ms and pulse amplitude was 30 mV. The detection limit for DOPAC was 1 μM at a potential of +0.055 V. Dihydroxyphenylethylene glycol (DOPEG) was detected at +0.08 V (LOD = 0.3 μM).

4 INSTRUMENTATION

The measurement of neurotransmitters and neurochemicals with microelectrodes requires specialized instruments capable of making often fast, repetitive (1−1000 Hz) and low-noise current measurements. Typical currents are in the low picoampere to mid-nanoampere range. There are no commercial instruments available that are capable of performing all of the aforementioned methods. We have tried to identify instrumentation that has the capability to carry out many of the different electrochemical recording methods.

4.1 Commercial

Several companies sell very versatile potentiostats that are often controlled by Windows-based software. Some of these are: Bioanalytical Systems – BAS 100B/W and CV-50W (West Lafayette, IN), Radiometer Analytical S.A. – Volta Lab 40 (Lyon, France), EG&G Princeton Applied Research – Model 394 (Wellesley, MA), and Cypress Systems, Inc. – CS-1200 (Lawrence, KS). These are all computer-controlled electrochemical analyzers capable of performing amperometry, CV, LSV, CA and a variety of other electrochemical methods. However, these instruments are more suited to microelectrode characterization studies, as they cannot perform many of the fast cyclic waveforms and currently they are not capable of analyzing and storing repetitive measures at 1−100 Hz recording rates.

Axon Instruments, Inc. (Foster City, CA) produces a potentiostat called the Gene Clamp 500 that is ideal for fast amperometric recordings. This system can be linked to commercially designed software for data analysis and storage. In addition, the Dagan Corporation (Minneapolis, MN) makes the Chem-Clamp that is suitable for amperometric recordings. There are additional commercial patch-clamp amplifiers that can be used for amperometric recordings. These amplifier systems are generally used for single cell recordings involving very rapid (<50 ms) current measurements.

Several companies market systems designed for high-speed in vivo electrochemical measurements. All of these instruments are optimized for rapid recordings using microelectrodes, but they cannot perform all of the aforementioned methods. SOLEA Tacussel (Villeurbanne, France) makes the Biopulse, which is an analog instrument for carrying out DPV, DNPV and DPA measurements. Cypress Systems sells the EI-400, which is a low-noise potentiostat that is generally used for FSCV measurements. It now has an internal waveform generator and custom, Windows 98-based software is available. P.D. Systems (West Molesey, Surrey, UK) sells the Millar Voltameter, which is an analog system designed primarily for FSV recordings. GMA Technologies, Inc. (Vancouver, Canada) markets a microcomputer-controlled potentiostat called the E-Chempro electrochemical instrument. This instrument can carry out LSV and CA recordings. Harvard Apparatus (Holliston, MA) now markets the IVEC-10, which is a microcomputer-controlled system for performing HSC, FSCV, FCV and amperometry. This system is a “turn-key” microcomputer-controlled potentiostat that has menu-driven software that is very easy to use. The current availability and capabilities of all of the aforementioned instruments should be gained from the manufacturers and laboratories that use these instruments.

4.2 Laboratory Designed

Many laboratories build or modify their in vivo electrochemical recording systems. The typical laboratory-designed system consists of a two-stage amplification system, a general-purpose potentiostat, an external waveform generator (if required), and an output device such as a strip chart recorder, sample and hold amplifier, and/or a microcomputer. The preamplifier is located as close as possible to the microelectrodes to minimize noise. The second amplifier is often located within the potentiostat. Software can be written or commercially available programs can be employed to store the data. External waveform generators can cause excessive noise in these
systems, therefore proper grounding and shielding must be used.\(^\text{[12,49]}\) Low-pass filtering can be used to eliminate high-frequency noise. This can be done using analog filters or can be carried out digitally using microcomputer software.

5 PREPARATIONS

By far the largest number of voltammetric recordings in CNS tissues have been carried out with respect to the nigrostriatal and mesolimbic DA pathways in the CNS of rats, mice, monkeys and guinea pigs.\(^\text{[1,2,4–7,9–14,16–20,22]}\) Voltammetric measures of DA have involved studies of electrical stimulation of the medial forebrain bundle and the effects of drugs that alter DA neurons in anesthetized rats and more recently in free-moving rats.\(^\text{[7,12,14,16,20,22,42,57]}\) The low extracellular levels of DA, NE and 5-HT have limited voltammetric studies of resting levels or basal levels of the neurotransmitters, which can be carried out with microdialysis methods. This has resulted in the extensive use of electrical and chemical stimuli to cause the release of DA so that it can be reliably measured. In contrast to the extensive number of studies of DA, there is a growing body of data regarding NE and 5-HT release from brain areas of the rat such as the hippocampus, substantia nigra, raphe nucleus, cerebellum, locus coeruleus and the dorsal raphe.\(^\text{[3,6,8,17,19,21,23]}\)

5.1 Cells in Culture

Wightman et al.\(^\text{[91]}\) introduced the concept of using fast amperometric recordings to study release of neurotransmitters, such as NE, from single cells. This is a rapidly growing area of study that uses \(\leq 5\) µm diameter disk recording electrodes coupled with amperometric or FSCV recordings to study properties of quantal release from individual cells in culture. A number of studies have been carried out on PC-12 cells, adrenal chromaffin cells, mast cells and engineered cells.\(^\text{[26–32,63,91]}\) These studies demonstrate the very rapid recording capabilities of the amperometric recording methods. Although it can be argued that many of these cells are not necessarily good models of CNS neurons, a variety of mechanistic studies are being carried out to understand further the fundamental properties of exocytotic release.

5.2 Brain Slices/Tissue Pieces

Perhaps one of the most rapidly growing areas using voltammetric recording techniques involves the use of brain slices from rats and mice. This methodology has a number of advantages over studying the CNS using anesthetized or freely moving animals. First, the slice preparation allows for visual control of all electrode placements. This is particularly advantageous when one is studying layered structures such as the hippocampus and hard-to-hit nuclei such as the substantia nigra and the dorsal raphe.\(^\text{[3,6,8,19,70]}\) Secondly, the slice preparations can be superfused with known concentrations of drugs for pharmacological studies. Third, the slice preparation makes it easier to study the brains of smaller animals such as mice. Finally, the slice preparation is unanesthetized tissue. Disadvantages involve the fact that outputs and inputs to brain structures are severed and that the viability of the slices can be a problem.

5.3 Whole Animals

Anesthetized rats have been used extensively to study the dynamics of DA neuronal systems using voltammetric techniques.\(^\text{[4,5,13–18,25,42]}\) Potential disadvantages of this preparation are the effects of anesthesia on the measurements and the inability to know the exact concentrations of drugs that affect CNS function. However, the anesthetized preparation is still powerful for studies of the more intact CNS.

The other major preparation for voltammetric studies involves the use of freely moving animals. In these studies the recording electrodes are often implanted days prior to measurement or a microdrive cannulae system is attached to the skull of the rat.\(^\text{[7,10,11,22,48,64–66,92]}\) These measurements often involve the use of special miniature potentiostats that are placed close to the animal’s head.\(^\text{[7,22,93]}\) Studies have been carried out to measure electrically-evoked release of DA and potassium-induced release of DA. In addition, a number of studies in freely moving rats have been carried out regarding the effects of drugs of abuse, such as cocaine and amphetamine. These studies are very time-consuming compared with brain slice or cell culture studies, but hold the promise of understanding more of the underlying properties of neurotransmitter signaling in freely moving and behaving rats.\(^\text{[93,94]}\)

6 APPLICATIONS

The majority of in vivo voltammetric studies involves the insertion of the microelectrodes into the brain regions of interest in the intact brain or brain slices (see Figure 1). In the case of cells in culture, the microelectrodes are positioned as close as possible to individual cells. Voltammetric measurements are then started to achieve a stable background. Once stable measurements are recorded, the effects of an event such as electrical stimulation or chemical stimulation of the neurons or...
cells is triggered and studied. Additional events are triggered to determine the effects of drugs used to alter the neuronal systems. The numerous applications and results obtained with these methods are beyond the scope of this article. We suggest that the interested investigator should read additional review articles and book chapters that concentrate on applications of this technology.  

6.1 Release of Neurotransmitters and Neurochemicals

The major reason for the development of in vivo electrochemical recording methods was to measure the release of neurotransmitters such as DA, NE and 5-HT in the intact CNS. Because of the very low basal release levels of these neurotransmitters, the majority of in vivo voltammetric studies to date have relied on ways of activating the release of these compounds from nerve endings, varicosities and dendrites by using electrical stimulation. In addition, chemical stimuli such as d-amphetamine, excess potassium, veratridine, and tyramine have been extensively used to cause the release of neurotransmitters. Moreover, in freely moving animals, systemically administered drugs and even self-administered drugs have been used to activate release processes. An example of the dramatic differences seen between potassium-evoked release of DA and d-amphetamine-induced overflow of DA which were recorded from a rat striatal brain slice is seen in Figure 3. These data also demonstrate the power of the temporal resolution afforded by these recording techniques.

6.2 Uptake/Reuptake and Diffusion

The major mechanism for inactivating released neurotransmitters is through membrane-bound proteins known as transporters. These efficient proteins shuttle the released neurotransmitter back into the neuron and inactivate the signal produced by the neurotransmitter. Voltammetric methods are ideally suited to studying the function of the DA, NE and 5-HT neuronal transporters. This is carried out using FSCV and HSC in whole animals and brain slices, and RDEV in brain minces or cells. In addition, the diffusional properties of DA, NE and 5-HT in different brain regions can be studied by these methods. This is an emerging area of study, which requires the speed and spatial resolution of the voltammetric methods. An example of the measurement of DA uptake in brain slices of the rat striatum and the effects from cocaine is seen in Figure 4. Interestingly, Wightman and co-workers have developed a model based on electrical stimulation of the slice or intact animal that allows for measurement of both release and uptake parameters in the same preparation.

7 QUANTIFICATION AND IDENTIFICATION ISSUES

Perhaps the greatest controversy that has surrounded voltammetric measurements in CNS tissues and cells in culture concerns the identity of the detected molecules. Although voltammetric methods are inherently selective compared to many methods because of the relatively few electroactive compounds present in brain tissues and cells coupled with the use of low-oxidation potentials to limit the number of analytes that can be measured (see Table 1), there has always been concern that “you don’t know what you are measuring with the in vivo voltammetric recordings.” Unlike microdialysis methods that use powerful separation techniques such as HPLC to separate molecules prior to detection, the microelectrodes
can see a number of molecules at the same time. This can confound the interpretation of in vivo voltammetric data. This has prompted the extensive development of electrode coatings (see below) to enhance further the selectivity of the microelectrodes for neurotransmitters or neurochemicals of interest. In fact, the real challenge for future development of microelectrodes is to develop microelectrodes and methods that are specific to a given molecule. In reality, any coating produces a diffusion layer that slows the response time of the microelectrode. This has limited the use of surface-modified electrodes for certain studies, such as rapid single cell recordings. However, electrode surface coatings that can solve some of the specificity problems are still under development.

7.1 Recording Methods

The best tools to use to identify further the detected molecule during fast recordings (≥1 s) have involved the use of FSCV, FCV and the HSC recording methods. As pointed out in section 3, the reduction/oxidation current relationship gives signatures for the detection of DA or 5-HT as compared to interferents such as AA and monoamine metabolites such as 5-HIAA and DOPAC. For example, DA yields distinctive cyclic voltammograms with the rapid voltammetry methods as well as distinctive reduction/oxidation current ratios using HSC recordings. This is true for the measurement of 5-HT as well. Confirming the detection of NE versus DA is more difficult. These chemical “signatures” are reliable measurements because they are fundamental properties of the detected compound.

7.2 Electrode Coatings

Electrode coatings to enhance the selectivity of microelectrodes for certain analytes and to make them sensitive to compounds that are not readily oxidized or reduced is a large area of scientific growth in the area of microelectrode development. In addition, such coatings can protect the surfaces of microelectrodes from fouling. Unfortunately, such layers can decrease the response times of the recordings, due to the diffusion layers created by these surface coatings.

7.2.1 Nafion™

Nafion™ is a Teflon® derivative that has sulfonic acid groups substituted into the polymer matrix. The sulfonate groups are negatively charged and this property has been used extensively to repel anions from electrode surfaces and prevent microelectrodes from fouling. Nafion™ films are one of the most widely used methods for improving the selectivity of voltammetric recordings in CNS tissues. As well as repelling anions, Nafion™ is thought to concentrate cations like DA at the electrode surface. Nafion™ is commercially available as suspensions in alcohol (5%, Aldrich Chemical Company). Electrodes are simply dipped into this mixture or Nafion™ is electroplated on to the electrode surface. Many methods of drying have been investigated including air drying, use of heat guns, and oven baking. The effect upon electrode sensitivity of the various coating and drying methods can vary between laboratories and experimenters. However, Nafion™ has been consistently used to enhance the selectivity of CFES or carbon monofilament microelectrodes by ≥100: 1 for DA, NE and 5-HT compared with AA, uric acid, DOPAC and 5-HIAA. The tradeoff with Nafion™ is the thicker the coating, the greater the selectivity for cations versus anions but the slower the response time.

7.2.2 Porphryin Coatings

(Poly)phenylenediamine (PPD) has been used as a coating to achieve selectivity and prevent fouling on electrodes. Selectivity is attained due to size exclusion. The electropolymerized coating has holes that allow small molecules like NO and H2O2 to diffuse to the electrode surface to be oxidized while blocking larger organic molecules such as DA from the electrode. The ortho, para, and meta-isomers of phenylenediamine have been investigated as well as combinations with catechol and resorcinol. We have developed a microelectrode based on a Nafion™-coated, o-phenylenediamine-modified CFE to measure NO selectively. Good selectivity over ascorbate, DA and nitrite has been observed. HSC (resting potential (E0) = 0, applied potential (Emax) = +0.9 V) were used to measure NO selectively.

Overoxidized films have been proposed as a substitute for Nafion™ films. When oxidized, polypyrrole is a cationic conducting polymer. When overoxidized, the cationic groups are replaced by carbonyl and carboxylic acid groups. These oxygen-containing groups repel anions such as ascorbate while attracting cations like DA. These electrodes were shown to be more sensitive to DA than Nafion™-coated electrodes with FSCV.

7.2.2 Porpyrin

A phorpyrinic-based microsensor for measuring NO was introduced by Malinski and Taha. Polymeric porphyrin was electrochemically deposited using CV on to carbon fibers from monomeric nickel tetrakis(3-methoxy-4-hydroxyphenyl)porphyrin (TMHPP). NO showed a peak at +0.63 V while NO2− had a peak at +0.8 V. A layer of Nafion™ was used to overcome the nitrate (NO2−) interference. DPV and amperometry were used to measure
NO with detection limits of 20 and 10 nM (signal-to-noise ratio = 3), respectively. The tip of certain types of microelectrode can be made small enough to penetrate individual cells. This sensor has been applied to measurements of NO in rat brain and in arteries.

7.2.3 Enzymes

Enzymes can be coated or immobilized on to electrodes to measure analytes that are not electroactive. This is another area of major growth in this field. The analyte is enzymatically converted to an electroactive product, which can be monitored at the electrode surface. Enzymes are often very selective for a particular substrate, which contributes to the selectivity of such enzyme-based sensors.

Oxidase and dehydrogenase enzymes are commonly attached to the surfaces of the microelectrodes. Oxidase enzymes produce hydrogen peroxide as one of their products and the oxidation of hydrogen peroxide is monitored at the electrode. Glucose, lactate, choline, and glutamate oxidase enzymes have been made commercially available. Microelectrodes for all of these molecules have been reported. Because oxygen is consumed in the reaction, microelectrodes built around this scheme sometimes have noticeable oxygen dependence. The second class of enzyme is dehydrogenase enzymes. They oxidize the substrate while reducing NAD$^+$ (nicotinamide adenine dinucleotide (oxidized form)) to NADH (nicotinamide adenine dinucleotide (reduced form)). Schemes for detecting NADH have been developed. An excess of enzyme is usually immobilized on to the electrode to increase sensor lifetime.

7.2.3.1 L-Glucose

Much work has been done to develop sensors to measure L-glucose. This research has been motivated by the need to monitor continuously blood glucose levels of people suffering from diabetes. Typically, amperometry with an applied potential between +0.6 and +0.7 V is used to measure peroxide at a platinized carbon, platinum or platinum iridium electrode. Using this microelectrode design, glucose has been measured in the rat brain.

7.2.3.2 Lactate

Similarly, lactate oxidase can be used to convert lactate into electroactive peroxide. Enzyme-modified CFEs have been used to measure lactate in the rat brain.

7.2.3.3 Choline

Peroxide can be measured at a carbon electrode by using horseradish peroxidase and an osmonium poly(vinylpyridine) redox polymer to shift the recording potential to $-0.1$ V versus SSCE. In this scheme, leaching of enzymes and the redox mediator is minimized. Another advantage is that interferents are minimized due to the low recording potential. A miniaturized version of this sensor was applied to the measurement of local injections of choline in rat brain. Choline oxidase was included in the polymer to sense choline. The detection limit was 1 µm for choline and response times were from 2 to 30 s.

7.2.3.4 L-Glutamate

By using dehydrogenase enzymes, detection of NADH or NAD(P)H (nicotinamide adenine dinucleotide phosphate (reduced form)) can be used to track changes in glutamate. However, high over-potentials are required to oxidize NAD(P)H (+1.1 V at carbon and +1.3 V at platinum). High over-potentials are undesirable because of surface fouling, oxidation of interferents present in the sample, and high background currents. The major challenge is to oxidize NADH or NAD(P)H at lower potentials. Electron mediators, which lower the required potential to that of the mediator, have been employed for this purpose. Alvarez-Crespo et al. have described a glutamate sensor based upon a modified carbon paste electrode that was coated with PPD. The nonconductive PPD film not only limits interferents from reaching the electrode and inhibits leaching of soluble species from the electrode surface, but in this case it allowed a lower potential (0 V versus Ag/AgCl reference) to be used for detection of the NAD(P)H produced from the glutamate dehydrogenase enzymatic reaction. An LOD of 3.8 µM was observed. Curulli et al. coated electrodes with 1,2-, 1,3-, 1,4-diaminobenzene (DAB) and 4-aminobiphenyl in the presence of pyrroloquinolinequinone (PQQ) using CV to obtain a layer through which only small molecules can pass to the electrode surface. POQ acts as an electron mediator for oxidation of NADH. Assembling and evaluation of new dehydrogenase enzyme electrode probes obtained by electropolymerization of aminobenzene isomers and PQQ on gold, platinum and carbon electrodes were examined. The use of the electropolymerized layer increased selectivity. POQ made the electrodes capable of catalyzing the oxidation of the reduced form of NADH at a potential of +0.2 V. Glutamate dehydrogenase was entrapped in the polymer, which made the electrode sensitive to glutamate with a detection limit of 5 µM.

Enzymes can also be immobilized on to the electrode surface using glutaraldehyde as a cross-linker. Pan and Arnold developed a glutamate sensor consisting of a Pt electrode (diameter = 1.6 mm) coated with Nafion™ followed by glutaraldehyde cross-linked glutamate oxidase. The anionic polymer Nafion™ was used to repel anions such as ascorbate while allowing hydrogen peroxide to be detected at the electrode surface. They reported an LOD of 0.3 µM with linearity up to 800 µM.
Entrapment of the enzyme within a polymer matrix has also been employed. O’Neill et al. have reported a glutamate sensor based on a 60-µm diameter platinum wire electrode that was dip-coated in a glutamate oxidase solution (200 units mL⁻¹, phosphate buffer, pH 7.4). α-Phenylenediamine was electropolymerized to entrap the enzyme. This method was an efficient use of enzyme compared to copolymerization.

Enzymes can also be covalently attached to the electrode surface. Avidin was used to attach biotin-modified enzymes to a biotin-modified CFE. In addition, membranes with immobilized enzymes have been attached to larger electrodes.

Elimination of interferents is generally done using coatings of Nafion, cellulose acetate, and PPD. Enzymes themselves can be used to eliminate interferents. Hu and Wilson et al. developed a glutamate electrode based on a two-enzyme design. Selectivity was obtained by coating the Pt–Ir wire (diameter = 0.17 mm) with the anionic polymers Nafion and cellulose acetate and incorporating ascorbate oxidase into the enzyme layer. Ascorbate oxidase removed the interferent AA. Excellent sensitivity and selectivity were reported; however, the two-enzyme design gave the sensor a larger oxygen dependence.

8.2 Fiber Optic Sensors

Fiber optic sensors have been used to measure neurotransmitters. Light of a desired wavelength is directed through a single optical fiber or a bundle. The light interacts with the chemical sensing end of the probe that is in contact with the sample. Light that has been modified by the compound of interest is collected with the same or different fibers then measured at a detector. Optical detection has the potential advantage of reduced electrical noise compared to electrochemical detection. In addition, multiple wavelengths can be used to identify compounds selectively. The disadvantage is that they are in general less sensitive than electrochemical detection and the instrumentation involved often precludes their use in freely moving animals. In addition, the sizes of fiber optic probes are too large for recordings of single cells. Fiber optic sensors have been reported for many compounds including NO and glutamate.

To date, voltammetric-based recording methods have been more widely utilized for neurochemical detection than fiber optic sensors.

1 Historical Review
2 Analysis
Abbreviations and Acronyms
References

The term “carbohydrate analysis” tends to have a different meaning for the different types of carbohydrates. For low-molecular-weight molecules (monosaccharides and simple oligosaccharides) it is generally taken to mean their separation and quantification, whereas for larger molecules and glycans derived from glycoproteins and glycolipids it may involve these factors but it is primarily the determination of the structure that is usually important. There are a number of electronic resources that are available to help clarify the rather specialized language used by the carbohydrate analyst and to provide databases of carbohydrate structures and nuclear magnetic resonance (NMR) spectra (Table 1).

Carbohydrates form a very diverse group of molecules usually made up from basic structures that commonly have a backbone of five or six carbon atoms and possess several alcohol groups and a hemiacetal or, more rarely, a hemiketal group. Less commonly found are carbohydrate units containing a nine-carbon backbone, whereas those with seven and eight carbons are sometimes found in bacteria. There are a number of isomers possible for these structures. As an example, a carbohydrate with six carbon units (CH$_2$O)$_6$ may be an aldehyde or a ketone. The aldehyde form has four chiral centers allowing 16 distinct entities. These units (one less chiral position may consist of 32 structurally different residues at the molecule’s periphery. Alternatively, there may be sequence and linkage heterogeneity as found in heteropolysaccharides or the molecular weight heterogeneity of homopolysaccharides. Polysaccharides are inherently highly polydisperse.

Each natural glycan appears to have one of three main purposes: as a food store; playing a structural role; or as a bearer of information in molecular or cellular recognition. Their structure determines, and will be determined by, their use. Although it is recognized that some simple low-molecular-weight glycans play a structural role as part of glycoproteins where they may alter the secondary, tertiary, and quaternary structure, many structural glycans are relatively stable, of high molecular weight, anisotropic and have a single backbone with little or no complex branching. Food glycans are easily hydrolyzed and have a high proportion of nonreducing termini. Information-bearing glycans often have very complex but specific and relatively low-molecular-weight structures. Carbohydrates play a major part in all living organisms. Understanding the structure of carbohydrates helps our understanding of these biological roles.

The analytical problems surrounding the carbohydrates are clearly orders of magnitude more difficult than that of protein analysis. Indeed, it is apparent that for many polysaccharides no two molecules are likely to be identical and the concept of “structure” must be interpreted differently from that for proteins. There is a further level of complexity if the conformation of the carbohydrates in solution is sought because, in contrast to protein structures, these are generally not fixed but fluctuate widely and may change irreversibly during isolation or with changes in the temperature, solvent, pH, ionic strength, concentration or co-solutes.

Fortunately, although the analytical task remains formidable, the full range of monosaccharide, ring size and linkage diversity is not found, with most glycans being constructed out of a very limited subset of possible molecular building blocks (Figure 1). For example, not counting equilibrium structures, there are 30 different D-glucose dimers and 1120 different D-glucose trimers possible.

Figure 1 The commonest monosaccharides present in glycans, with the base form of their common abbreviations in parentheses: (1) α-D-glucose (Glc); (2) β-D-glucose; (3) α-D-galactose (Gal); (4) β-D-galactose; (5) α-D-mannose (Man); (6) β-D-mannose; (7) α-D-glucosamine (GlcN); (8) N-acetyl-β-D-glucosamine (GlcNAc); (9) N-acetyl-α-D-galactosamine (GalNAc); (10) N-acetyl-β-D-galactosamine; (11) α-L-fucose (Fuc); (12) N-acetyl-α-D-fucosamine (FucNAc); (13) α-D-glucuronic acid (GlcA); (14) β-D-glucuronic acid; (15) α-D-galacturonic acid (GalA); (16) β-D-galacturonic acid; (17) α-L-arabinose (Ara); (18) β-L-arabinose; (19) α-D-xylene (Xyl); (20) β-D-xylene; (21) α-L-iduronic acid (IdoA); (22) α-L-rhamnose (Rha); (23) 3,6-anhydro-α-D-galactose; (24) 3,6-anhydro-α-L-galactose; (25) β-D-fructose (Fru); (26) N-acetyl-β-L-talosaminuronic acid; (27) α-L-galactofuranose; (28) β-D-galactofuranose; (29) N-acetyl-α-neuraminic acid (NeuAc); (30) β-L-arabinose; (31) 3-deoxo-α-D-manno-oct-2-ulopyranosonic acid (Kdo); (32) β-D-mannuronic acid (ManA); (33) α-L-guluronic acid (GulA). Structures (17), (18), (25) and (28) are furanoses, the rest being pyranoses. Structures (1–6), (25), (27) and (28) are hexoses, (7) is an aminohexose, (8–10) are N-acetamidohexoses, (11), (12) and (22) are deoxyhexoses, (13–16), (21), (32) and (33) are hexuronic acids and (17–20) and (30) are pentoses. Structures (2), (4–6), (8), (10), (11), (14), (15), (17), (20), (22) and (29) are relatively common, whereas (7), (12), (16), (18), (23), (24), (26–28) and (30–33) are found only rarely, the remainder occurring occasionally. Other monosaccharide residues (not shown) are found very rarely, with microorganisms in particular producing a wide variety of rare monosaccharide units. Compounds are also found as derivatives with some or all of sulfate, phosphate or acetyl groups or as their methyl ethers.
but only six dimers and three trimers are commonly encountered (maltose, cellobiose, isomaltose, gentiobiose, α,α-trehalose, sophorose, cellobiose, maltotriose and panose). However, the analysis of polysaccharides and glycans remains challenging and must be tackled in a systematic manner.

1 HISTORICAL REVIEW

It is surprising that carbohydrates, given the present difficulties in their structural analysis, were amongst the first natural products to be isolated, quantified and to have their structures determined. The straightforward, if flawed, analysis of mixtures of glucose, fructose and sucrose, using the rotation of polarized light, facilitated the early studies on enzyme kinetics. This determination was used by Berthelot\(^1\) in 1860 in the first proof of the catalysis of biological reactions by nitrogenous material (enzymes), by Sørenson\(^2\) to show the effect of pH on enzyme (invertase) activity in 1909 and by Michaelis and Menten\(^3\) in 1913 to underpin the early development of enzyme kinetics. The determination of specific rotation is still used as a confirmatory technique and in those rare instances where mixtures of both anomeric forms of component sugars are present in complex glycans and their ratio is required.

Before powerful chromatographic methods evolved, a number of colorimetric assays were developed involving the reducing power of the low-molecular-weight sugars or by coupling to suitable molecules such as phenol after acidic dehydration.\(^4\) Some of these assays were developed further to give different responses with different monosaccharides. They remain of considerable use to this day, particularly where just the concentration of a known carbohydrate is required. Where selectivity is required, these assays are replaced by colorimetric or fluorimetric assays involving enzymatic conversions.
Early analytical work in the 1940s and 1950s centered on the use of paper chromatography to separate the component sugars from acid-hydrolyzed polysaccharides, with much effort being applied to the selection of the developing solvents and the detection methodology. Although paper chromatography is easy and inexpensive, can separate a wide variety of structural types, including oligosaccharides and some polysaccharides, without their prior derivatization and generally ensures that no components go undetected, it is only rarely used nowadays. In the 1960s and 1970s, paper chromatography was developed into thin-layer chromatography with its greater resolving power, and in the 1980s to high-performance thin-layer chromatography. These improved methodologies possess very much greater resolving power and improved quantification but are little used in modern carbohydrate analysis, apart from their important utility for separating glycolipids, having been generally outclassed by high-performance liquid chromatography (HPLC) techniques.

Another development from paper chromatography was the use of column chromatography. Initially these consisted of charcoal or cellulose, and then the ion exchange and ion exclusion matrices that have evolved over the years into the high-performance columns used today. Although these separation techniques generally work well, a major problem has been in the detection of carbohydrates. Unlike proteins, carbohydrates have no natural ultraviolet absorption, color or fluorescence. Free aldehyde or ketone groups do absorb ultraviolet light but only below about 200 nm, and then rather inefficiently. This does allow their detection but only when noninterfering eluents, such as pure water or acetonitrile, are used. Refractive index detectors have been commonly used but these are rather insensitive and easily confused by changes in eluent composition such as solute gradients. Many pre- and post-column derivatization processes have been devised in order to facilitate sensitive spectrophotometric determination. Relatively recently, the introduction of pulsed amperometric detection has driven forward the use of HPLC for carbohydrate analysis. This methodology in which about 1% of carbohydrate alcohol groups are oxidized at a gold electrode when in alkaline solution, has proved to be both sensitive and reliable. In this system the gold electrode is utilized and cleaned about once every 1 s by a series of oxidative and reductive electrical pulses. This methodology has been coupled to the development of alkali-stable anion exchange resins for use in high-performance anion exchange chromatography (HPAEC).

Improved separation techniques are constantly being developed with very high resolutions and capable of distinguishing even quite closely related glycans. When coupled to detection by mass spectrometry (MS), they can form a powerful part of the carbohydrate analytical toolbox.

Gas chromatographic methods were commonly used for the analysis of monosaccharides in the 1960s, when their high sensitivity and resolution placed them well ahead of the, then current, liquid chromatographic methods. Their development depended on methodology, based on trimethylsilylation or the acetylation of their alditols, to convert the inherently involatile carbohydrates into volatile derivatives. Although currently often replaced by HPAEC, gas chromatography methods are still used because the technique is well understood. Gas chromatography is particularly useful for the analysis of partially methylated alditol acetates produced by methylation analysis and where coupled MS is necessary.

The absolute configuration (D or L) of monosaccharides was an important part of early analyses, involving a considerable degree of effort and ingenuity. This was achieved via the relatively large-scale purification of hydrolysis-derived monosaccharides, followed by their chemical characterization. Where possible, the configuration was decided or confirmed by X-ray crystallography. Once sufficient absolute structures had been established, materials were determined by comparison of their specific optical rotation. Much simpler chiral chromatographic methods now exist, but absolute configurations are only rarely specifically established, because most work is on materials where this is already known or may be assumed from, for example, the use of enzymes of known specificity.

Linkage analysis was first determined, in the 1940s, by means of the analysis of fragments produced by periodate. This method, which depends on the ability of periodate to cleave between neighboring unlinked alcohol groups, is still used occasionally to help solve otherwise intransigent problems. A useful development of the technique is the Smith degradation, where (nowadays) borohydride reduction of the resultant aldehydes and chromatography of the resultant alcohols follow oxidation. The introduction of a powerful and efficient methylation procedure by Hakomori in 1964 allowed linkage positions to be determined more explicitly, and developments of this methodology, coupled with the use of gas chromatography/mass spectrometry (GC/MS), are commonly used today. Linkage analysis normally must be combined with other techniques such as partial hydrolysis and NMR if more than localized structural arrangements are to be determined.

Determination of the anomeric configuration has always been achieved by the use of specific enzymes. The use of enzymes also confirms the absolute configurations. Sequence analysis has always been problematic. Glycoprotein glycans, where the monosaccharide units are linked together in precise and generally well-understood sequences, can be investigated successfully by the controlled and sequential addition of specific
exoglycosidases. Advances over the years have concerned the range of available enzymes and the more detailed knowledge concerning their specificity. Although suitable enzymes are often not easily available, this is an important area of research and there is likely to be considerable progress in the future. Recently, NMR has been used to distinguish the anomic configurations and sequence of oligosaccharides in many cases.

The determination of the molecular weight of carbohydrate-containing polymers has been decidedly difficult until recently. This is because they may be very large, they hold on to large amounts of water, they may possess very anisotropic structures and there are few “standard” molecules with known structures that are suitable for comparison with the unknown substances. Analytical ultracentrifugation was commonly used in the 1940s and 1950s but is rarely used nowadays. Size exclusion chromatography has proved to be very useful in determining the size of proteins but is of limited use for large carbohydrates, except as a means of separation, owing to the very different ways in which carbohydrate-containing molecules behave in solution and the typical inapplicability of the available calibration molecules. Although light scattering was one of the earliest methods available, in the 1940s, for determining molecular weights in solution, it is only the recent introduction of multi-angle laser light scattering (MALLS) that has made this technique widely accepted. MALLS allows the relatively straightforward and accurate determination of the absolute weight-averaged molecular weight ($M_w$) of large carbohydrate-containing molecules without the need for standards. In its most powerful mode it can be used as part of HPLC detection to monitor continuously the molecular weights and shapes of the materials eluted. Number-averaged molecular weights ($M_n$) and polydispersity ($M_w/M_n$: a measure of the breadth of the molecular weight distribution) can also be estimated by this method.

Although NMR has been used for many years, the one-dimensional spectrum of most carbohydrates is generally too complex to be assigned fully. There remain, however, sufficient “reporter” groups for much useful information to be obtained. In particular, the monosaccharides present, their anomic conformations and ring size (i.e. pyranose or furanose) and some indication of the linkages present are usually determinable. With the development of multidimensional techniques and powerful (600-MHz) instrumentation, NMR is proving to be a dominant technique for determining complex protein structures but has not yet had a similar level of success with large carbohydrates. The spectra for medium or large molecules are extremely complex and difficult to interpret but NMR has proved valuable for determining or confirming the structure of oligosaccharide fragments, and a database of structural assignments is being built up. NMR is capable of determining the sequence, linkage position and anomic configuration. Although it is, potentially, a most powerful method for determining the conformation of carbohydrates, this use of NMR is still in its infancy with respect to glycans. A major drawback for the technique is its lack of sensitivity, particularly as many polysaccharides have limited solubility, form gels or are relatively inflexible in solution. Often such molecules give rise to poor spectra owing to their unfavorable relaxation properties.

The specific binding of antibodies or lectins to carbohydrates has been used to show the existence and availability of particular substructures within complex carbohydrates and may be used in carbohydrate separation and purification. As the family of known lectins has grown over the years and their characterization has improved, they have become useful tools for distinguishing between closely related glycans without the need for full analyses.

MS can be used to determine the molecular weight of low- and medium-molecular-weight carbohydrates of up to about 10 kDa. For some molecules, tandem mass spectrometry (MS/MS) can also give compositional, sequence and linkage information. Little success has been reported for higher molecular weight polysaccharides, perhaps due to the inherent heterogeneity of carbohydrate samples. The main restriction with MS is that isomeric monosaccharides, such as glucose and galactose, cannot be distinguished. The technique can be very sensitive, with only subpicomole amounts being required. Electrospray ionization MS may be used as a detection system for HPLC, capillary electrophoresis and capillary isoelectric focusing. Such systems are very powerful in that they can achieve two-dimensional separations based on MS and chromatography.

The area of conformational analysis remains one of the most intransigent problems in carbohydrate analysis. This is partly because of the vast number of possible local conformational potential energy minima possible: for just four 1→4-linked hexopyranoses joined together, there are about $3^{25}$ (approximately 1 trillion) possible local potential energy minima. For medium and large glycans the number of local minima is so vast that it is possible for only a fraction of the conformations to be sampled during their existence. In addition, a significant number of these conformations are in deep potential energy wells. Most sizeable molecules will therefore consist of mixtures, with little chance that any two molecules are conformationally identical unless they possess long-range order such as the presence of helices. NMR is capable of determining the conformation of these carbohydrates but will deliver time-averaged conformations that may or may not be true reflections of the actual conformations. In such circumstances, although there may be little meaning to any one “averaged” conformation, knowledge concerning the typical conformational motifs can be a very useful
aid in discussing the glycan’s molecular interactions and functional properties. Additionally, where multiple conformational states exist and are in rapid equilibrium (i.e. usually), the lack of unique torsional angles and time averaging of the NMR data combine to blur the conclusions that can be drawn. Molecular modeling is helping for making inroads into solving this conformation problem. Its present restricted usefulness, due to the vast memory and computational requirements, is being rapidly overcome.

2 ANALYSIS

No single method suffices for the analysis of glycans, in contrast to protein analysis where either X-ray crystallography or NMR may be sufficient. In addition, crystalline protein structures appear to be very similar to their structure in solution, whereas carbohydrates that take up very different conformations with no clearly defined structure in solution may form a regular structure in the solid state. Isolation and purification are also more likely to affect the structure and conformation of high-molecular-weight carbohydrates than proteins. The structural determination of most complex carbohydrates utilizes a wide variety of methodologies, often including the use of enzymes, methylation analysis, MS and NMR; these methods complement and reinforce each other. A complete structural determination of an unknown glycan, subsequent to its isolation and purification, involves the following stages, which are often undertaken approximately in the order given:

- determination of the constituent monosaccharides, their absolute configuration (D or L), their ring size and any derivatization they have undergone, such as sulfation, methylation or acetylation;
- determination of the molecular size or molecular size distribution;
- determination of the anomic configuration of the linkages (α or β);
- determination of the linkage positions between the monosaccharide units;
- determination of their sequence, including any repetitive pattern in the structure and the degree of any heterogeneity;
- determination of any preferred conformation of parts or all of the molecule(s) present.

The more important analytical methods appropriate to different carbohydrates are given in Table 2. A modern carbohydrate analytical facility clearly involves the availability of a range of expensive instrumentation and staff skilled in a variety of chemical and biochemical techniques.

* Methods involving cleavage produce monosaccharides and/or oligosaccharides.

This section of the Encyclopedia (i.e. carbohydrate analysis) has articles on all the main classes of carbohydrates selected on the basis of class rather than methodology. Each class (Monosaccharides and Sugar Alcohol Analysis; Disaccharide, Oligosaccharide and Polysaccharide Analysis; Proteoglycan and Acidic Polysaccharide Analysis; Glycoprotein Analysis: Using Nuclear Magnetic Resonance; Glycoprotein Analysis: General Methods and Glycolipid Analysis) has its own particular analytical direction, although all involve analysis of their component monosaccharides. They may use related methodology for part of their analytical schemes but they also use their own characteristic methods based on their distinct structures and properties.

ABBREVIATIONS AND ACRONYMS

- GC/MS: Gas Chromatography/Mass Spectrometry
- HPAEC: High-performance Anion Exchange Chromatography
- HPLC: High-performance Liquid Chromatography
- MALLS: Multi-angle Laser Light Scattering

Disaccharide, Oligosaccharide and Polysaccharide Analysis

Anne D. Blackwood and Martin F. Chaplin
South Bank University, London, UK

1 Introduction

Disaccharides are compounds in which two monosaccharide units are joined by glycosidic linkages. Oligosaccharides are broadly defined as carbohydrate polymers containing up to twenty residues. According to the number of units, they are called trisaccharides, tetrasaccharides, pentasaccharides etc. where the number of units is the degree of polymerization (DP, e.g. tetrasaccharides have a DP of 4). The borderline between oligosaccharides and polysaccharides is not precise, however, and oligosaccharides are generally molecules with precisely defined structures whereas polysaccharides have inexact defined length or structure.

Polysaccharides form a diverse and complex family of biological macromolecules. The source and structure of some commonly occurring polysaccharides are given in Table 1. They are essentially condensation polymers of monosaccharide units joined by glycosidic linkages. Polysaccharides may be composed of a single sugar unit (termed homopolymers) or may contain two or more constituent monosaccharides (heteropolymers) joined in a variety of ways. The polymers may be linear, branched or even cyclic in nature and this has important consequences for their physicochemical nature. Polysaccharides are abundant in nature and found in nearly every living organism. They can function as storage polysaccharides, such as starch in plants and glycogen in animals, structural elements in the cell walls of bacteria and plants and skeletal elements in arthropods. They can also be found linked to proteins and lipids, and have been implicated in cell–cell recognition and molecular targeting. Glycoproteins and glycolipids will not be reviewed here as they are discussed in separate articles.

Polysaccharides occurring in nature often have high molecular weights, frequently well in excess of 1000 kDa. They are usually polydisperse in nature and may contain a wide range of closely related structures. The generic term for all polysaccharides is glycans. They are often individually classified by adding ‘an’ to the end of the constituent prefix for the parent sugar, for example glucans for polymers of glucose, xylans for polymers of xylose and so on. However many common unsystematic names, such as cellulose, pectin, amylose and inulin, are still in use alongside the systematic ones. Heteropolymers are commonly classified

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
by placing the branched or lowest unit first and the parent backbone sugar last; for example, rhamnogalactans are polymers with a galactose backbone and rhamnose side-chains.

Polysaccharides can be classified in terms of their monosaccharide composition, type of glycosidic linkages present, sequence of units along the backbone, the relative degree and spacing of the substituted groups along the chain and the DP. Many of the structure–function relationships of carbohydrates have been poorly elucidated due to the difficulty in extraction, purification and fine structure characterization of these complex polymers. However the availability of highly specific glycosidases to break down the polysaccharides backbone and recent advances in techniques such as high-performance liquid chromatography (HPLC), MS and NMR spectroscopy, have enabled a number of fine structures to be elucidated. It is hoped that detailed characterization of these molecules will lead to a greater understanding of their biological role.

Disaccharides and oligosaccharides form a varied class of hydrophilic low-molecular-weight molecules (Table 2). A number of these are nonreducing sugars used as mobile stores to provide for the synthetic needs of their source organism without risk of nonspecific reactions otherwise associated with free reducing termini. Others are mainly found as the hydrolytic products of polysaccharides and other glycans.

In order to discover the structure of glycans, it is necessary to determine not only the monosaccharides present, their linkage positions and sequence, but also the anomeric configuration of linkages, the ring size (furanose or pyranose), the absolute configuration (D or L) and to identify any other substituents present. There is no one method that can be used to determine the fine structure of polysaccharides; instead we must use a combination of analytical methods to gain as much information as we can. For analysis of disaccharide and oligosaccharide mixtures, separation and quantification techniques such as colorimetric and enzymatic assays (section 4), TLC, section 5.1.1) or HPLC, (section 5.1.2) may be applied. For polysaccharide analysis separation and extraction techniques (section 2), component analysis (section 3), methylation analysis (section 5.2), glycosidic hydrolysis (section 5.3), MS methods (section 7.1) and

2 EXTRACTION

The first step in structural polysaccharide analysis is the extraction and separation of a single polysaccharide species from extraneous components. Polysaccharide material must be separated from low-molecular-weight material such as inorganic salts and fat and from other high-molecular-weight material commonly found associated with polysaccharides such as protein. Unless the level of these extraneous components is already known in the sample material, then these must be determined prior to extraction. The key stage is the selective extraction of the appropriate polysaccharide in as high a yield as possible, with minimum effect on the polysaccharide fine structure. The amount of carbohydrate present at each stage of the purification procedure can be monitored using a non-specific carbohydrate assay such as the phenol–sulfuric assay.\(^1\)

Water-extractable polysaccharides can be solubilized in aqueous solutions, and low-molecular-weight material removed by dialysis, ultrafiltration or treatment with ion exchange resins. Other carbohydrate components may be selectively degraded at this stage using the appropriate glycosidase e.g. starch can be removed by enzymatic degradation with α-amylases. The enzymes used must not cause degradation of the polysaccharide of interest. Polysaccharide material can then be isolated from aqueous solutions by graduated fractionation with, for example, ammonium sulfate or ethanol or by lyophilization.

Water-unextractable polysaccharide material can often be solubilized in alkali. If required, extraneous components can be removed prior to alkaline extraction e.g. fat can be solubilized in an appropriate solvent such as chloroform–methanol (95:5 v/v) using Soxhlet apparatus and protein can be denatured by suspension in aqueous sodium dodecylsulfate. The extraction step must be carefully designed to minimize base-catalyzed hydrolysis, β-elimination and Lobry de Bruyn–Eckstein transformations (degrading the reducing end of the molecule), which may otherwise occur under alkaline conditions. It is useful to use an extractant, if possible, which will preferentially select for the carbohydrate of interest. This will simplify the purification procedure. An example is the use of saturated barium hydroxide solution, containing a critical concentration of sodium borohydride, to selectively extract insoluble arabinoxylans from wheat cell wall material.\(^2\) If a sufficiently selective extractant cannot be found, then it may be necessary to introduce further purification steps, such as separation on ion-exchange resins e.g. diethylaminoethyl (DEAE)-cellulose, in order to separate polysaccharide species or provide a sample of sufficient homogeneity for analysis.

3 COMPONENT ANALYSIS

There are many different stereoisomers of hexoses or pentoses that are possible but fortunately for the analyst only a few are commonly found in polysaccharides. These are listed in Table 3. Analysis of the monosaccharide composition of carbohydrates requires complete hydrolysis of all the glycosidic linkages present in the sample. Polysaccharides containing furanose units such as fructans and arabinans can be completely and rapidly hydrolyzed by treatment with mild acid. Polysaccharides containing pentose sugars as pyranoside units and even more so those containing hexopyranoside units are rather more resistant to hydrolysis. They are still relatively easily hydrolyzed using e.g. 2 M HCl for a period of 2–5 h at 100°C. If the polysaccharide material is not water-soluble, it may be pre-treated with 72% sulfuric acid for a short period at low temperature to facilitate solubilization followed by dilution and hydrolysis as above. Some residues involved in very acid-resistant glycosidic linkages may not be released by mild acid hydrolysis and may require more stringent techniques. For example uronic-acid-containing polysaccharides, particularly with the aldobiuronic acid type of linkage, require combined treatment of methanolysis (2 M HCl in methanol) followed by hydrolysis with trifluoroacetic acid to release all the components present.\(^3\) The glycosidic linkages of aminosugar residues are also very resistant to acid hydrolysis. In general α-glycosidic bonds are more acid-labile than β-glycosidic bonds.

Analysis of the released monosaccharide components can be identified, after any appropriate derivatization, by a number of chromatographic techniques including TLC, gas chromatography (GC) or HPLC. Driven by improvements, particularly in the type and sensitivity of detectors available, the method of choice for analyzing component sugar composition is probably high-performance anion-exchange chromatography coupled with pulsed amperometric detection (HPAEC/PAD).\(^4\) Column chromatography of the monosaccharides and their derivatives are discussed in

4 ENZYME AND COLORIMETRIC ASSAYS

There are a number of rapid and convenient colorimetric assays available for determination of carbohydrate groups in intact molecules. These tend to be based either on the determination of the number of reducing end groups, or on the creation of a chromophore by complexation with the sugar under acidic dehydrating conditions. General carbohydrate assays such as the phenol–sulfuric acid assay are often used to monitor the carbohydrate content of column effluents to give a quick and quantitative measure of, for example, free and combined glucose.\(^1\) Calibration with appropriate standards is necessary, as different sugars will give varying color responses with this assay. More specific assays can be used to detect the presence of particular kinds of sugar such as hexoses, pentoses, uronic acids or aminosugars. For example, pentose can be measured with a modified version of the L-cysteine–sulfuric acid assay,\(^6\) uronic acids using a modification of the carbazole assay\(^7\) and hexoses by any of the general carbohydrate assays. For reducing sugars either the Nelson–Somogyi method\(^7\) or the more convenient dinitrosalicylic acid assay can be used.\(^8\) As with many of the less specific colorimetric assays the reducing sugar assays do not differentiate between sugars and can give varying color responses. Accurate quantitative determination of mixtures of monosaccharides or hydrolyzed polymer structures may be better determined using the more powerful column chromatography techniques such as HPLC.

There are a number of specific colorimetric enzymatic assays available for the determination of individual carbohydrate groups. These are ideal for a quantitative analysis of known carbohydrates in, for example, complex mixtures of food samples. There are a large number of enzymes available for oligosaccharide and polysaccharide analysis, a full summary of which is given in section 5.4. For example determination of starch or sucrose may be achieved by enzymatic hydrolysis to monosaccharides with glucoamylase or invertase respectively, followed by enzymatic determination of glucose using the hexokinase/dehydrogenase assay.\(^9\) There are commercially available kits for the enzymatic detection of sucrose, maltose, lactose, and starch. There are also an increasing number of commercial biosensors available not just for glucose analysis\(^10\) but also for other carbohydrates such as maltose, sucrose and starch for which suitable enzyme systems exist.\(^11\) These are particularly useful for monitoring the effluent in on-line automated HPLC processes.

5 BIOCHEMICAL METHODS OF ANALYSIS

5.1 Separation Methods

5.1.1 Thin-layer Chromatography

TLC can be used as a convenient and semi-quantitative method of analyzing the oligosaccharide hydrolysat of polysaccharides. It can provide a rapid preliminary screening of mixtures of monosaccharides and oligosaccharides giving an indication of the component sugars present and of their relative amounts. This gives valuable information about the composition of the native polysaccharide. Due to the sensitivity of the procedure, even minor components can be detected. Carbohydrates have been separated using a number of different solid supports and an array of solvent systems,\(^12,13\) but no single method is universal and trial-and-error must sometimes be adopted to find appropriate separation conditions. Thin-layer plates can be prepared in the laboratory but, for reproducibility, are best purchased pre-coated with microcrystalline cellulose or silica gel as the solid support. Sugars are separated essentially by liquid–liquid partition, with some element of adsorption in the case of silica gel. Impregnation of silica gel with inorganic salts has been shown to improve resolution with sugar separations. For more complex mixtures of sugars where the \(R_f\) values are small, resolution can be improved by performing multiple ascents where the chromatogram is eluted, dried and re-eluted using the same eluent a number of times.

The relative movement of the carbohydrate (\(R_f\)) and the efficiency of separation may be affected by laboratory conditions such as humidity, temperature and chromatographic tank size. Variations in the coating batch and coating method may also adversely affect \(R_f\) values. Hence, the \(R_f\) values for standards are always determined alongside the unknowns and values quoted in the literature used for guidance only. In general, the lower the molecular weight or the more hydrophobic the carbohydrate the higher the \(R_f\) value.

Detection of carbohydrates for TLC is commonly based on dehydration and complexation after the chromatogram has been sprayed with an appropriate reagent and heated to 100–150°C for 5–10 min. Suitable reagents include those based on diphenylamine/aniline/phosphoric acid or naphthoresorcinol/ethanol/sulfuric acid. A wide variety of colored responses is given, depending on the nature of the sugars present. TLC can be used semi-quantitatively using scanning densitometric analysis. The interpretation of such results may be misleading as color development will vary with spray technique, temperature and duration of heating and traces of salts, proteins and other impurities present in the sample.
TLC has been used to separate complex mixtures of cyclodextrins and their derivatives on silica gel.\(^{(14)}\) Cyclodextrins, their glucosyl derivatives, and linear oligosaccharides were separated by eluting with mobile phases containing aqueous ammonia and either acetonitrile (ACN) or 1-propanol (Table 4). Compounds with different numbers of substituents on the cyclodextrins could be clearly separated, though the system did not allow separation of individual isomers.

Oligosaccharides may be purified on the milligram scale by high-performance thin-layer chromatography (HPTLC). HPTLC plates are available pre-coated from commercial suppliers, and are characterized by a much narrower particle size and particle size range resulting in improved resolution. Analysis by densitometry is also more satisfactory with HPTLC plates than conventional TLC plates.

in the type and sensitivity of detectors available, have seen it become the method of choice for many different types of analyses. In practice, though, GC is still in common use and there are many good examples of disaccharide and oligosaccharide separations in the literature.\(^{(15,16)}\) SEC, used for the separation of polysaccharides and preliminary screening of mixtures of oligosaccharides and unknown samples, is discussed in section 6.1.

The term ‘HPLC’ is conventionally applied to columns having plate numbers above 2000, the typical range being 2000–20000. For analytical applications, spherical packing materials generally offer better reproducibility and column stability over irregular-shaped particles. Particle sizes ranging from 3 to 20\(\mu\)m are available. The most popular particle size for analytical columns is 5\(\mu\)m, but the use of 3-\(\mu\)m particles in short columns is increasing. The retentivity and capacity of a packing material is related to its pore size. For most general analytical methods (analyte molecular weights less than 3 kDa) pore sizes of between 6 and 13 nm are typical.

The type and commercial availability of HPLC columns and detectors has expanded tremendously in recent years. For carbohydrate analysis the two most common types of packing materials are amino-bonded silica-based materials and metal-loaded polymeric substrates such as cross-linked styrene–divinylbenzene. The silica-based packing materials have a high rigidity and do not swell in any solvent. Their weakness is limited stability in aqueous mobile phases at high pH. The polymeric-based packings are more compressible, but they are compatible with all mobile phases including the entire aqueous pH range. Both the inorganic and the polymeric based materials offer a wide range of separation modes including reversed phase, ion exchange, hydrophilic interaction, hydrophobic interaction and SEC.

Some of the commercially available columns and typical analyses associated with them are given in Table 5. It should be borne in mind that there are many commercially available columns that will perform similar functions, and the list in Table 5 is by no means exhaustive. Choice of appropriate column for given separation is often due as much to personal experience, cost and availability of materials as choice of separation chemistry.

In reversed phase chromatography, where separation is by means of hydrophobic interactions, the stationary phase is nonpolar and the mobile phase is polar.\(^{(17)}\) Typical stationary phases are silica-based bonded phases with aliphatic hydrocarbon ligands, for example octadecylsilane (ODS or C\(_{18}\)). Other packings for reverse phase chromatography include graphitized carbon or styrene–divinylbenzene. The mobile phase for carbohydrates is commonly a mixture of ACN and water. Graphitized carbon columns show exceptional physical and chemical stability and can be used throughout the

<tr>
<td><strong>Separation based on hydrophilic interaction chromatography (HILIC)</strong> is another popular method of carbohydrate analysis. HILIC uses polar stationary phases, such as microparticulate silica, with mobile phases ranging in polarity from water through ACN to hexane. Weak anion-exchangers based on bonded phase silicas containing primary, secondary and tertiary amines are the most common type of packing used for carbohydrate analysis. Retention increases with the hydrophilicity of the stationary phase and the hydrophobicity of the mobile phase. An alternative to using amino-bonded stationary phases for the separation of neutral oligosaccharides has been recently demonstrated using a β-cyclodextrin bonded phase column. Separation of neutral oligosaccharides derived from starch, cellulose, pullulan, xylan, inulin, and mann can be achieved using ACN–water mobile phases. Retention times are dependent on both the monosaccharide composition and glycosidic linkage type. The fast separation of inulin-derived oligosaccharides, up to DP 13, in ACN–water phases is demonstrated in Figure 2(a), with the effect of a higher ratio of ACN in the mobile phase shown in Figure 2(b). The β-cyclodextrin bonded phase column appears to have similar selectivity but greater durability compared to the amino-bonded phase silica gels. Ion-exchange chromatography, whole pH range. Such a column has been shown capable of separating nine isomeric disaccharides using gradient elution with dilute alkali containing small amounts of ACN (Figure 1).</td>

F = fructose, GF2 = 1-kestose (DP 3), GF3 = DP 4, etc. using a β-cyclodextrin bonded phase column (Cyclobond I, 250 mm x 4.6 mm i.d.); operated at room temperature and 1 ml min⁻¹ flow rate with refractive index (RI) detection. S represents the solvent peak. (Reprinted from J. Chromatogr., A, 648, 131–137, © 1993 with permission from Elsevier Science.)

Based on strong anion-exchange resins (high-performance anion-exchange chromatography methods, HPAEC), is a powerful technique, which is discussed separately in section 5.1.3.

Monosaccharides, produced by enzymatic or chemical hydrolysis of polysaccharides, are often derivatized prior to HPLC analysis by the introduction of stable chemical groups such as 1-phenyl-3-methyl-5-pyrazolone (PMP). This can improve both resolution and sensitivity. A list of some common derivatives used is available in the article on Monosaccharides and Sugar Alcohol Analysis.

Ultraviolet (UV) detectors are not commonly used for carbohydrate analysis, though it is possible to monitor sugars directly at wavelengths below 200 nm. However at such short wavelengths, low sensitivity and background interference levels make the use of UV detectors often impractical. RI detectors work on the principle of differential refractometry and have, until recently, been the mainstay of HPLC carbohydrate detection. However, RI detectors are temperature dependent and cannot be used with a gradient, as they are extremely sensitive to changes in mobile phase concentration. RI can be useful for routine analysis of, for example, food samples where sensitivity in excess of 0.05% w/v is not generally required. If greater sensitivity is necessary then alternative detectors must be found. Pulsed amperometric detectors now offer much more versatility and sensitivity than RI detectors. These detectors are commonly used in tandem with anion-exchange chromatography, and are discussed in more detail in the next section.

5.1.3 High-performance Anion-exchange Chromatography Methods

In recent years HPAEC has become the method of choice for the separation of disaccharide and oligosaccharide mixtures. Coupled with PAD, HPAEC/PAD offers high resolution at picomole sensitivity. Specifically developed for the analysis of carbohydrates, HPAEC/PAD takes advantage of the weakly acidic nature of carbohydrates under alkaline conditions for highly selective separations on strong anion exchange resins. Anion-exchange chromatography of the partially ionized carbohydrates is carried out on polymeric, nonporous pellicular resins that are ideally suited to conditions of high pH. Separation is due to the degree of ionization of individual saccharides, but also can be based on anomers, positional isomers and molecular size. Retention times can be manipulated by altering the strength of the sodium hydroxide concentration or by addition of the more strongly eluting acetate anion. Typical analysis conditions will use mobile phase concentrations of 1–150 mM NaOH (pH 11–13) with gradient elution in sodium acetate for more strongly bound analytes.

Carbohydrates can be electrochemically oxidized at the surface of a gold or platinum electrode by the application of a positive potential (E₁). The initial current produced is proportional to the analyte concentration. As the oxidative carbohydrate products will lead to poisoning of the electrode surface over time, it is necessary to clean the electrode surface between measurements using a pulsed sequence of potentials. The electrode potential is raised to a sufficient degree to oxidize the surface and remove carbohydrate oxidation products (E₂). To reduce the surface back to gold, a third potential is then applied (E₃). A typical cyclic sequence for carbohydrate analysis by pulsed amperometry is shown in Figure 3.(21) Although Dionex were the first company to commercially manufacture pulsed amperometric detectors, a number of other companies now produce their own versions.
Figure 3 Typical cyclic sequence for pulsed amperometry. The potentials \(E_0, E_1, E_2\) and duration of the phases are shown.

The advantage of detection with PAD for carbohydrates is that no pre- or post-column derivatization is necessary. Sample preparation is also simplified because only oxidizable analytes will be detected by PAD, and the sensitivity for carbohydrates is orders of magnitude greater than for possible contaminant species.\(^{21}\) Although HPAEC is often carried out at high pH, some separations are better carried out at neutral or acidic pH. While PAD sensitivity will decrease below pH 11, this problem can be circumvented by the post-column addition of base, usually 300–500 mM NaOH, to maintain pH through the detector. Unlike RI detectors, PAD is not sensitive to changes in salt concentration. It does show slight sensitivity to variable low NaOH concentrations such that post-column addition of base may also be necessary when running low concentration NaOH gradients.

There are a number of good reviews on HPAEC/PAD techniques in the literature.\(^{22,23}\) The technique has been used to estimate the chain length of different amylpectins after enzymatic digestion by isoamylase (Figure 4).\(^{24}\) Although the relative detector response changes with the DP, this can be overcome by using saccharides with appropriate chain lengths as standards. Recently a method coupling SEC with HPAEC has been developed to distinguish between highly branched and linear oligoglucans, as well as linear isomeric glucooligosaccharides.\(^{25}\) This method may be very useful in overcoming problems separating smaller oligosaccharides from the larger polymeric mass during the early stages of enzymatic digestion of polysaccharides.

5.1.4 Capillary Electrophoresis

Capillary electrophoresis (CE) is a relatively new technique that provides rapid, highly efficient separations for carbohydrates.\(^{26,27}\) Electrophoresis is the movement of charged substances in a conductive medium, usually aqueous, under the influence of an applied electric field. Charged species are separated on the basis of their electrophoretic mobility (charge : mass ratio) and the electroosmotic flow (migration of positive buffer ions to the cathode under the influence of the applied field). Separation can be manipulated by changing either buffer composition or pH. The technique is also applicable to neutral polysaccharides, which can be charged either through complexation with for example borate ions, or by raising the pH of their microenvironment. CE is complimentary to separation of oligosaccharides by GC and HPLC techniques. Like HPLC, it is suited to the analysis of both polar and nonpolar carbohydrates and it may replace many of the HPLC techniques in the near future. CE offers fast and efficient separation, relatively affordable and durable capillary columns, requires small sample volumes and has low reagent consumption. However, it is not generally useful for preparative scale applications.

CE is available in a number of modes including capillary zone electrophoresis (CZE), isoelectric CE, and micellar electrokinetic CE. Typical CE equipment consists of high-voltage power supply, buffer reservoirs, a capillary column, and a detector. CE is usually performed using fused silica capillaries that are 50 or 70 \(\mu\)m i.d., 375 \(\mu\)m o.d. and between 30 and 100cm long. Fused silica capillaries are commercially available from a number of suppliers and much longer ones have been used in GC for a number of years. The major limitation in the use of CE for carbohydrate analysis, as with other techniques, has been detector sensitivity. Advances in separation and detection techniques in the last five years including PAD and fluorescence detection has seen yoctomole \(\left(10^{-24}\right)\) sensitivity become a realistic target.\(^{28}\)
Separation of the raffinose family of oligosaccharides (Figure 5) has been demonstrated using the capillary zone method of electrophoresis, where the carbohydrates are charged using their cis-diol borate complexes. Partial purification using ion exchangers before CZE appeared essential to achieve good separation (Figure 5b). Separation by high-performance CE of the borate-complexed oligosaccharides offered several advantages over HPLC separation using RI methods, including on-column UV detection, ease of operation, low cost per analysis and the use of nontoxic chemicals.

5.2 Methylation Analysis

Methylation analysis is one of the most commonly used techniques in structural carbohydrate chemistry. Methylation analysis will give information on the positions at which sugar residues are substituted and their relative abundance in the polysaccharide, though it gives no information on the sequence that these residues appear in, nor on their anomic conformation. Methylation analysis involves methylation of all the free hydroxyl groups in the polysaccharide, hydrolysis of the methylated polysaccharide to its component parts, reduction of these methylated monosaccharides to alditols, acetylation of the alditols, and subsequent qualitative and quantitative analysis of the partially methylated alditol acetate derivatives by GC or GC/MS. The positions of the free hydroxyl groups in the partially methylated sugars indicate where the residue was substituted.

The main problems associated with the technique are incomplete methylation of the polysaccharide, oxidative degradation of some hydroxyl groups and contamination from ‘impure’ reagents and solvents. Methylation analysis is commonly based on a modification of the Hakomori procedure, where alkoxide groups are readily generated by the presence of a strong nucleophile ensuring complete methylation of all free hydroxyl groups. The polysaccharide is dissolved in dry dimethyl sulfoxide (DMSO) in the presence of a strong base such as sodium hydride, 1-butyl lithium, potassium tert-butoxide or powdered sodium hydroxide generating production of the dimsyl anion. Methylation of the alkoxide groups is usually carried out with methyl iodide (Scheme 1). Latterly methods based on the use of potassium dimsyl have become more widespread, and it is reported to give at least equal or better results than the sodium salt.

At the end of the methylation reaction, water is added and the polysaccharide can be recovered from the aqueous phase after extraction with chloroform. The methylated polysaccharide is then reduced to its component sugars by hydrolysis (trifluoroacetic, hydrochloric or sulfuric acid may be used). At this stage the components have free hydroxyl groups in the positions where they were linked to each other and methyl ether groups where the original polysaccharide had free hydroxyl groups. Reduction of the methylated monosaccharides in sodium borodeuteride, to label the reducing ends, is followed by peracetylation with acetic anhydride in pyridine (1 : 1 v/v). Finally the volatile, partially methylated alditol acetates are analyzed by GC coupled to a mass spectrometer (GC/MS, see Scheme 1).

For oligosaccharide substrates it is often advantageous to convert the reducing termini of the oligosaccharides to their alditols before methylation, in order to reduce side reactions.

5.3 Periodate Oxidation

Periodate oxidation is another important tool in structural polysaccharide chemistry and can be used to determine glycosidic linkage. In the first step periodate oxidizes adjacent hydroxyl groups in carbohydrate residues. Formic acid is produced when the polysaccharide unit contains three hydroxyl groups on adjacent carbon atoms. Oxidation is followed by reduction to polyalcohols with sodium borohydride followed by mild acid hydrolysis.
Degradation of periodate-oxidized amylose, after reduction and hydrolysis, is demonstrated in Scheme 2. Since periodate oxidation requires adjacent free hydroxyls, if the glucan in Scheme 2 was (1→3)-linked then only the terminal residues at both the reducing and non-reducing ends would be oxidized. Periodate oxidation is normally carried out in the pH range 3–5 to avoid acid hydrolysis and to minimize side-reactions involving non-selective oxidations. Periodate can cause over-oxidation of certain products causing misinterpretation of results. Where the main structural features of a polysaccharide are already known, periodate oxidation can be a useful method.

An important modification of this procedure, the Smith degradation, selectively degrades polysaccharides to oligosaccharides or smaller polysaccharides. Controlled hydrolysis with dilute acid is carried out at ambient temperatures. The acetals of oxidized sugar rings are the most labile during the hydrolysis step. The products may range from the low-molecular-weight products shown in Scheme 2 to monosaccharide, oligosaccharide and polysaccharide glycosides that can be usefully put through the procedure again.

### 5.4 Hydrolysis with Specific Glycosidases

Glycosidases are an important tool in structural determination because of their ability to specifically cleave carbohydrate linkages in disaccharides, oligosaccharides and polysaccharides. It is their ability to cleave specific...
residues without side-reactions, yielding unmodified oligosaccharides that is important for the determination of native polysaccharide structure. Mixtures of di- and oligosaccharides can then be separated and identified by column chromatography and NMR. Knowledge of the mode of action of the enzymes used allows a prediction for native polysaccharide fine structure. This technique is hindered only by the availability of suitable, single-activity enzymes. Complete hydrolysis of a complex polysaccharide will involve the use of more than one type of enzyme. A list of some of the glycosidases commonly used in polysaccharide analysis is given in Table 6.

### 6 MOLECULAR WEIGHT ANALYSIS

Oligosaccharides and polysaccharides usually possess one, and only one, reducing end group per molecule. Where these can be quantified, the number of molecules present can be determined. If the total carbohydrate present is also determined, the average chain length and the molecular weight may be calculated. There are very sensitive colorimetric assays available for reducing end groups including the use of oligosaccharide dehydrogenase, an enzyme specific for reducing end groups.(34) Alternatively, quantitative ¹H NMR using the terminal anomeric reporter groups may determine them. These methods allow molecular weights up to about 20 kDa (NMR) to over 100 kDa (colorimetric) to be determined. However, the presence of even tiny amounts of monosaccharide impurities may render the result invalid due to the number averaging of the resultant molecular weights.

The molecular weight (M) of pure macromolecules may be determined by ultracentrifugation, so long as both the sedimentation coefficient (s) and the diffusion coefficient (D) are determined under the same conditions, using the relationship shown in Equation (1).

\[
\frac{s}{D} = M \left(1 - \overline{v} \rho \right) \frac{1}{RT}
\]

where T is the temperature (K), R is the gas constant, \( \overline{v} \) is the partial specific volume (the effective volume per unit mass) of the solute and \( \rho \) is the solution density. Although this method is still sometimes used, the method remains arduous compared with SEC and laser LS methodology.
6.1 Size Exclusion Chromatography
SEC has proved to be a useful technique for separating carbohydrates on the basis of their molecular weight. Molecules are eluted in order of decreasing molecular size from a stationary phase containing a wide range of different size pores, allowing greater access and hence slower elution for smaller molecules. SEC is particularly successful in separating members of oligosaccharide families where it often allows the exact number of component sugars to be determined (Figure 6). Where the oligosaccharides come from a mixture of oligosaccharide families, the assignment of molecular size is less reliable in the absence of known standards. SEC is less successful at determining the molecular size of polysaccharides where it depends on the use of similar carbohydrates, of known molecular weight, for calibration. Unless these molecules are monodisperse and have almost identical structures to those of the unknowns, the resultant calibration may be grossly in error. This has been shown to be the case where the molecular weights can be independently determined by, for example, LS (see section 6.2). Use of secondary calibration in the SEC, where polysaccharides of known molecular weight but dissimilar structure are used, has been shown to overestimate the molar mass of chitosans and capsular polysaccharides by two- and threefold (Figure 7). Improvement can be made if ‘universal calibration’ is used involving the use of the product of the intrinsic viscosity and the molecular weight ($\eta M_w$, a measure of the dynamic volume of the polysaccharide) in place of the molecular weight alone. However, this involves the additional use of a viscometric detector and gives incorrect results if the calibrating and unknown polysaccharides are of different conformational types (e.g. random coil versus stiff rod). Although high-performance size exclusion chromatography (HPSEC) uses columns having theoretical plate numbers of about 10,000, even under optimal conditions they are only capable of resolving polysaccharide peaks where there is at least a twofold difference in molecular weights or sizes present. There are two reasons for this: (1) the resolving power of SEC columns is relatively poor for high-molecular-weight polysaccharides, and (2) such polysaccharides usually consist of a range of molecular species with a wide molecular weight distribution. In spite of these limitations, SEC is proving to be a powerful technique for the analysis of polysaccharide polydispersity when used in combination with on-line LS molecular weight determination.

6.2 Light Scattering
Light is scattered from molecules in solution in a way that depends on the concentration and molecular size of the molecules present. This has been known for over 50 years but it is only recently that methods have become widely used for polysaccharides. In particular the use of MALLS has enabled the accurate nondestructive determination of the molecular weight, molecular weight distribution and radius of gyration of many polysaccharides without the need for known calibrating standards. When combined with the separating power of HPSEC, it forms an
important tool for the polysaccharide analyst. A typical SEC/MALLS system includes an RI detector, placed after the MALLS detector, for determining the concentration of the eluting polysaccharides. Generally there is no need for the simultaneous UV detection, which is so useful in the SEC/MALLS of proteins, as polysaccharides rarely possess absorbing groups.

LS from molecules in solution is described by Equation (2).\(^{139}\)

\[
\frac{Kc}{R_0} = \frac{1}{M_w} \left( 1 + \frac{16\pi^2}{3\lambda^2} (r_g^2) \sin^2 \left( \frac{\theta}{2} \right) \right. \\
+ f_4 \sin^4 \left( \frac{\theta}{2} \right) + \cdots + 2A_2c \right) 
\]

where:

- \( K \) is an optical parameter given in Equation (3).

\[
K = \frac{4\pi^2n^2(n_d/dc)^2}{\lambda^2N_A} \tag{3}
\]

- \( c \) is the sample concentration, calculated from the differential RI response, \( R_0 \) is the excess intensity of scattered light at angle \( \theta \), and \( M_w \) is the weight average molar mass (molecular weight, Equation 4).

\[
M_w = \frac{\sum n_iM_i^2}{\sum n_iM_i} \tag{4}
\]

where \( M_i \) is the mass of the \( i \)th polysaccharide chain and \( n_i \) is the number of chains with that mass.

- \( \lambda \) is the wavelength of the scattered light in vacuum.
- \( A_2 \) is the second virial coefficient, a measure of the solute-solute interaction. The \( 2A_2c \) term is usually negligible in SEC separations due to typically low concentrations.
- \( A_2 \) is characteristically about \( 1 - 2 \times 10^{-5} \text{mol} \text{ml}^{-1} \). At polysaccharide (\( M_w 10^6 \)) concentrations of about 1 mg ml\(^{-1} \), ignoring this term gives about a \( 2 - 4\% \) error. It may, however, be significant for charged polysaccharides at low ionic strength.

- \( N_A \) is Avogadro’s number, \( n \) is the RI. \( (dn/dc) \) is the RI increment of the solute, which is usually determined prior to HPSEC using a range of polysaccharide concentrations. This value varies between polysaccharides and is somewhat less (~0.13–0.15 ml g\(^{-1} \)) than that for proteins (~0.18–0.19 ml g\(^{-1} \)).

\( (r_g^2) \) is the z-average mean square of the radius of gyration (\( R_G \), Equation 5)

\[
R_G^2 = \langle r_g^2 \rangle = \frac{\sum n_iM_i^2\langle r_g^2 \rangle_i}{\sum n_iM_i^2} \tag{5}
\]

\( R_G \) reflects the average displacement of each residue from the molecular centre. Typically for a linear polysaccharide (\( M_w 10^6 \)) this would be approximately 6 nm if spherically packed (\( R_G = \text{radius} \times \sqrt{3/5} \), 940 nm if as an extended stiff rod (\( R_G = \text{length} / \sqrt{12} \)), and 17 nm (\( R_G = \text{unit length} \times \sqrt{\text{units}/6} \)) if as a random coil. The \( \sin^2(\theta/2) \) and higher terms (not shown in Equation 2) are not explicitly used as the determination of the molar mass and the radius of gyration involve extrapolation to zero angle. For smaller molecules with \( R_G \) up to 10 nm, the \( \sin^2(\theta/2) \) term is ignored as well as this simplification only introduces errors of less than about 1%. The lack of sensitivity to scattering angle at low \( R_G \) means that it cannot be accurately determined when smaller than about a sixtieth of the wavelength of the light used (i.e. \( <0.10 \text{nm} \)). Ignoring this term in \( \sin^2(\theta) \) allows single-angle LS (Equation 6) data (often at \( 90^\circ \)) to be used.

\[
LS = K_{LSC}M_w \left( \frac{dn}{dc} \right)^2 \tag{6}
\]

where \( K_{LS} \) is a detector calibration constant. As the RI signal (Equation 7) is given by

\[
RI = K_{RIC} \left( \frac{dn}{dc} \right) \tag{7}
\]

where \( K_{RI} \) is the instrumental calibration constant, the molar mass (\( M_w \)) can be determined from these two readings once the polysaccharide’s RI increment has been determined (Equation 8).

\[
\frac{1}{M_w} = K' \frac{dn}{dc} \frac{RI}{LS} \tag{8}
\]

\( K' \) is a calibration constant determined by using previously characterized similar polysaccharides.

At low angles, the angular dependence of LS depends only on the radius of gyration and is independent of molecular conformation or branching. This is of particular benefit in the study of polysaccharides, which may take up a wide variety of conformations in solution. Often the molecular weight and radius of gyration are determined by plotting \( (Kc/R_0) \) against \( \sin^2(\theta/2) \) (Zimm plot) to yield an often almost linear curve whose intercept gives \( M_w \) and whose slope at low angles gives \( \langle r_g^2 \rangle \). For branched polysaccharides the radius of gyration can provide a measure of the degree of branching if similar but unbranched polysaccharides are available. When repeated at various polysaccharide concentrations, or across a SEC run, other parameters such as the number average molecular weight (\( M_n \), Equation 9), polydispersity (Equation 10), molecular weight distribution and weight-averaged radius of gyration (\( \overline{R}_G \), Equation 11)
may also be determined.

$$
\overline{M}_w = \frac{\sum n_i M_i}{\sum n_i} = \frac{\sum c_i}{\sum c_i M_i}
$$

(9)

polydispersity = \frac{M_w}{\overline{M}_n}

(10)

$$
\overline{R}_i^2 = \langle r_i^2 \rangle = \frac{\sum n_i M_i \langle r_i^2 \rangle_i}{\sum n_i M_i} = \frac{\sum c_i \langle r_i^2 \rangle_i}{\sum c_i}
$$

(11)

$M_w$ is always greater or equal to $M_n$ so the polydispersity, which measures the breadth of the molecular weight distribution present, is always greater or equal to unity.

MALLS detectors simultaneously measure the LS at a number of angles and extrapolate via software to zero angle. There are also low-angle laser light scattering (LALLS) devices which only measure at very low angles ($^\circ$3–7). The choice between these systems depends on a number of factors including sensitivity to extraneous noise. It has been found that, for most polysaccharides, the molecular weights vary across HPSEC peaks (Figure 8). Molecular weights of polysaccharides that are insoluble in water can be determined using MALLS with other solvents (e.g. DMSO) without necessarily using HPSEC.

Even highly insoluble polysaccharides such as cellulose may be analyzed (e.g. in dimethylacetamide containing LiCl), if they can be dissolved in suitable solvents, although such solvents may not be compatible with the HPSEC matrices. MALLS detection may be used in conjunction with other HPLC separation techniques (e.g. reverse phase chromatography) but as it determines the weight-averaged molecular weight it will give less meaningful results if a wide range of molecular masses, or few species but with very disparate molecular masses, are present. MALLS can also be used for determining the molar mass and molecular weight distribution of oligosaccharides.(40)

7 PHYSICAL METHODS OF ANALYSIS

7.1 Mass Spectrometry

MS was one of the first methods used to investigate carbohydrate structure. Its principle of operation is to create gas-phase ions, separate them in space or time based on their mass-to-charge ($m/z$) ratio and to quantify them. Originally it assisted in linkage analysis by identifying the methylated alditol acetates produced in the methylation analysis of glycans and separated by GC. The electron impact/mass spectrometry ionization method (EI/MS), often utilized in GC, is highly energetic causing extensive degradation and, usually, the absence of molecular ions. This lack of molecular ions is of little importance as it is the fragmentation pattern that is so important to methylation analysis, clearly demonstrating which hydroxyl groups were free and have been methylated, and which were involved in linkages and have been acetylated. As EI/MS requires volatile samples, oligosaccharides are too polar unless derivatized. Development of the gentler fast atom bombardment ionization source allows oligosaccharides, both derivatized and underivatized, to be analyzed in a similar manner but where molecular ions and large fragments, produced by cleavage between the glycosidic units, are produced. The reducing end of oligosaccharides can be labeled with $^{18}$O for MS by catalyzed exchange with H$_2^{18}$O (e.g. by using 2-aminopyridine or other epimerization catalyst), enabling fragments involving this end to be distinguished. Larger oligosaccharides and polysaccharides may make use of the even milder ionization techniques involving matrix assisted laser desorption ionization (MALDI) and electrospray ionization (ESI). As these produce molecular ions without interference from breakdown products, the molecular weight distribution can be clearly demonstrated. MS must be combined with other methods of analysis, as it cannot distinguish between isomeric sugar residues and cannot easily provide the linkage and stereochemical information of NMR.
7.1.1 Fast Atom Bombardment/Mass Spectrometry

FAB/MS (fast atom bombardment/mass spectrometry) can be used optimally on nanomolar amounts of oligosaccharides and small polysaccharides up to about 15 kDa although usually requiring microgram amounts of oligosaccharides of less than about 5 kDa. Xe or Cs ion or Xe atom guns are all suitable for carbohydrates. Carbohydrates are generally, but not necessarily, derivatized by permethylation or peracetylation as then they are easier to purify, the sensitivity is improved by as much as two orders of magnitude and the fragmentation pattern is more predictable. However, the use of underivatized carbohydrates removes the risk of any loss of labile substituents. The spectra usually contain the molecular ions, which may be protonated or cationized with ammonium, sodium or potassium. This allows cyclic glycans, such as the cyclodextrins, to be identified, as their molecular mass is 18 (H₂O) less than the corresponding linear glycan. The major inter-glycosidic fragmentation processes may result in hydrolytic-like fragments from either side of the glycosidic link or elimination-like oxonium ion fragments from the anomeric side only (Scheme 3).

Two fragmentation pathways dominate the spectrum. Permethylated and peracetylated glycans cleave on non-reducing side of glycosidic bonds to give oxonium ions (Scheme 3a), a cleavage that is particularly favored by reducing side of glycosidic bonds to give oxonium ions. Permethylated and peracetylated glycans cleave on non-reducing side of glycosidic link or elimination-like oxonium ion fragments from the anomeric side only (Scheme 3). Two fragmentation pathways dominate the spectrum. Permethylation and peracetylation of glycans cleave on non-reducing side of glycosidic bonds to give oxonium ions (Scheme 3a), a cleavage that is particularly favored by N-acetyl-hexosamines. Native carbohydrates commonly give β-cleavage where a hydrogen atom is taken from the neighbor glycoside and retained on either the reducing (Scheme 3b) or nonreducing end (Scheme 3c). The residue masses are given in Table 7. Linkage analysis can be achieved from FAB/MS by the analysis of rarer cross-ring fragmentation products or by utilizing partial acid or enzyme hydrolysates. Anomeric configurations can be determined by FAB/MS due to the different rates of their chromium trioxide oxidation in peracetylated oligosaccharides, β-linkages are equatorial and are more rapidly oxidized than α-linkages so forming a keto-ester, breaking the ring, and resulting in a mass change of +14 (+O −2H).

7.1.2 Matrix-assisted Laser Desorption Ionization Mass Spectrometry

MALDI can vaporize and ionize large molecules and is capable of determining molecular weights, in exceptional cases, of up to m/z 300 kDa using time-of-flight (TOF) detection. It requires only femtomoles to picomoles of material, needs no sample derivation and tolerates more buffer and detergent than other MS methods. Although able to handle proteins, it has not had similar success, so far, with natural polysaccharides in the upper part of this range (>25 kDa) and seems to work best with oligosaccharides below 5 kDa (Figure 9). This may be partly due to the polydispersity of such samples and the inherently poor resolution of MALDI/TOF/MS.

MALDI ionizes by using a UV laser pulse to ablate a UV-absorbing matrix which carries some of the large molecules into the gas phase in an ionized form. The matrix commonly used for carbohydrates is 2,5-dihydroxybenzoic acid (DHB), although several other matrices (e.g. 3-aminoquinoline, α-cyano-4-hydroxycinnamic acid, 2-hydroxy-5-methoxybenzoic acid, 2,6-dihydroxyacetophenone) are often tried in order

![Scheme 3](image_url)

Scheme 3 The major inter-glycosidic fragmentation processes. (a) 'A type' cleavage; (b) β-cleavage with charge retention on the reducing end; (c) β-cleavage with charge retention on the nonreducing end. In β-cleavage the hydrogen atom has been abstracted from the position β to the glycosidic oxygen on the uncharged fragment and producing an enol/keto group (e.g. the 3-position in (b) and the 2-position in (c)) in unmethylated oligosaccharides.

Table 7 Exact mass data for carbohydrate residues in oligosaccharides and polysaccharides utilizing the most abundant isotopes; also given is the maximum number of free hydroxyl groups if the residues are not terminal (there will be one more if terminal) and the extra mass involved for each additional methylated and acetylated group.
to optimize the spectra. Anions, such as sulfate, are added by some workers in order to obtain negatively charged ions, which are analyzed by MS using the negative mode. The matrix is usually present in about a hundred-fold molar excess over the carbohydrate. Intact oligosaccharides can be recovered and sequenced directly, by MALDI/TOF, from sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE) separated glycoproteins. Gel pieces containing glycoprotein are denatured, reduced S-alkylated and endoglycosidase digested, then extracted with water, cleaned up using micro-columns, dried and subjected to MALDI/TOF. Neutral oligosaccharides give [M + Na]⁺ and smaller [M + K]⁺ peaks. Acidic residues, such as sialic and uronic acids, form both positive and negative ions and readily form salts with alkali metal ions resulting in multiple peaks. These adverse effects may be overcome by prior esterification. The mass accuracy of MALDI (0.1–0.01%) is generally lower than other MS methods, but the recent linking of the method to collision-induced dissociation/Fourier transform mass spectrometry (CID/FTMS) extends this to 0.001% for oligosaccharides.

7.1.3 Electrospray Ionization/Mass Spectrometry

ESI allows production of molecular ions directly from samples in solution and is thus suitable for direct interfacing to HPLC and CE. It is far less able to handle buffers and detergents than MALDI. Multiply charged ions are usually produced which is an advantage on naturally multiply charged proteins and glycoproteins (up to about 150 kDa) but a disadvantage on polydispersely neutral glycans. Although ESI has good sensitivity (picomole) and accuracy (0.005%), the m/z range of their normal quadrupole detectors is only up to 3 kDa allowing its use only on glycopeptides and smaller oligosaccharides and lipopolysaccharides.

7.1.4 Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) utilizes two or more mass selection devices in series so that the known ion from one analyzer may be selected and induced to give daughter fragments which are determined using a second analyzer. It can provide complete sequence, branching and linkage information. If higher energy collision-induced dissociation (CID) is achieved, the choice between pyranose and furanose ring systems may be distinguished due to carbon–carbon bond cleavage of the side chain leaving ring oxonium ions.

MS/MS can be used with FAB (fast atom bombardment), ESI and MALDI. The use of post-source decay (PSD) in MALDI/TOF is proving particularly useful for the linkage analysis of complex oligosaccharides where a database of spectral information can be built up, such as with glycoprotein N-glycans. Similar data can be obtained by ESI CID. This is because the extent and distribution pattern of fragments is highly reproducible. Multiple fragmentation occurs inter-glycosidically with retention of Na⁺ cationized charge on either the reducing or nonreducing fragment in a similar manner to that in FAB/MS (see section 7.1.1).

7.2 Nuclear Magnetic Resonance Spectroscopy

NMR is proving to be the most powerful technique for the structural analysis of oligosaccharides and polysaccharides. It is particularly useful in finding unusual and unusually substituted sugars. Each proton (¹H nucleus) attached directly to carbon in a monosaccharide has its own characteristic environment. However as the number of carbohydrate units increases in the molecule so does the number of magnetically distinct nuclei. Pentoses and hexoses in oligosaccharides and polysaccharides have eight or ten distinct protons per residue, respectively. Two or three, respectively, of these are associated with alcohol hydroxyl groups. This means that they have approximately the same number of protons as proteins of similar size; significantly more if the hydroxyl protons are counted in. They also have approximately the same number of carbon atoms. Nitrogen atoms are absent in most oligosaccharides and polysaccharides but, even where present in large amounts (e.g. in chitosans), there are significantly fewer than in similarly sized proteins. ¹H and ¹³C NMR spectra of carbohydrates may, therefore, be extremely complex. Additionally, many of these environments are often similar, giving a poor spectral dispersion with overlapping resonances. As in protein NMR, the low natural abundance of ¹³C (1.11%) and ¹⁵N (0.37%) and
these isotopes’ lower natural sensitivities compared to $^1$H ($^{13}$C, 1.6%; $^{15}$N, 0.1%), means that NMR utilizing these atoms is much improved if the carbohydrate has been isotopically enriched.

The key features of carbohydrate NMR are due to the downfield shifts (to higher ppm) due to the spatial proximity of oxygen atoms. As the anomeric carbon is bonded to two oxygen atoms, the anomeric (C-1) carbon ($^{13}$C) atoms and protons are easily distinguishable and provide important inroads into the structural determination. Other groups also provide well-resolved resonances. The methyl protons and carbon ($^{13}$C) atoms in deoxysugars are easily distinguishable and provide important inroads into the structural determination. The methyl protons and carbon ($^{13}$C) atoms in deoxysugars are upfield (i.e. at lower ppm) and the carboxylate carbon ($^{13}$C) atoms in uronic acids are downfield. Free amino groups give pH dependent shifts, upfield of hydroxyls, whilst N-acetyl and O-acetyl groups give upfield methyl groups.

In NMR the quality of the spectrum depends on two relaxation times. The longitudinal relaxation time $T_1$ (seconds) describes the rate at which the magnetization returns to equilibrium along the magnetic field ($z$ direction) and correlates with the overall rotational tumbling of the carbohydrate and its intramolecular flexibility. The transverse relaxation time $T_2$ (seconds) describes the rate of decay of the effective magnetization observed in the receiver ($xy$ directions) and correlates with the dynamic properties of the molecule (e.g. it reduces with increasing molecular size). Line width is inversely proportional to $T_2$. The large size of polysaccharides leads to slow tumbling, hence broad lines due to fast $T_2$ spin–spin relaxation. This reduces the sensitivity, broadens the spectral lines and generally results in poor performance of 2-D techniques that incorporate delays to allow coherence (same phase) transfer. Although spectral improvements can be achieved by heating (~70–85 °C), albeit with the introduction of extra ‘noise’, this may have conformational consequences. For example, multihelical structures give very poor spectra, which can be improved by heating and/or alkali but the treatment results in them having a different conformation. Cations (e.g. Ca$^{2+}$) may also cause gelling with carboxyl-containing polysaccharides, so reducing performance. A high viscosity is also associated with poor NMR spectra. In general, the larger the polysaccharide, the less resolved its NMR spectrum. Resolution may be improved by partial hydrolysis (e.g. 10 mM HCl, 100 °C, 10 min) but this may give fragments that are not representative of the original structure. For example, partial acid hydrolysis of arabinofuranosyl groups strips off the labile arabinofuranose groups leaving bare β-xylan chains. If available, partial hydrolysis using well-characterized endo-glycosidases is preferred.

Polysaccharides are usually run in D$_2$O – (H$_2$O). Working in D$_2$O eliminates the less well-defined exchangeable hydroxyl protons and the vast excess (110 M) of H$_2$O protons, although significant HOD (4.4 mM) resonance remains even in 99.996% D$_2$O solution. Intramolecular hydrogen bonding may be investigated by dissolving the carbohydrate in per-deuterated DMSO when the hydroxyl (and amine) protons do not exchange with solvent and give useful information. It must be noted, however, that sugars may behave differently in this solvent than in aqueous solution. Inter-residue hydrogen bonding is important in determining the overall conformations of carbohydrates but is difficult to determine by NMR. In some cases hydrogen bonding may be determined from proton exchange in mixed H$_2$O and D$_2$O solvents where hydrogen bonding may be quantified from the differential shifts in proton and carbon spectra.

The anomeric protons can provide information concerning the types of residues present, their anomeric (α or β) configuration and their ring size (pyranose or furanose). Details of the NMR spectra of many carbohydrates are available from a database. Although 1-D proton NMR spectra can be used as fingerprints to enable structural determination where database structures exist, they are generally too complex to fully assign even for relatively simple oligosaccharides (Figure 10a). $^{13}$C Spectra are simpler but are also usually too complex to use without the availability of fully assigned NMR spectra from suitable known structures for guidance. The structures of unknown carbohydrates generally demand a variety of through-bond correlated spectroscopy (COSY) and through-space nuclear Overhauser effect spectroscopy (NOESY) 2-D NMR techniques using high field spectrometers (600 MHz) for their elucidation.

Although NMR is an essentially nondestructive method relatively large amounts of material are required and may be lost or degraded if required for long periods. NMR is between three and six orders of magnitude less sensitive than MS. 1-D NMR requires between about 10 nmol (600 MHz) to 80 nmol (300 MHz) and 2-D NMR requires somewhat more. Oligosaccharides have small proton resonance linewidths when compared to proteins which allow 2-D NMR spectra to be obtained at low (~100 μM) concentrations.

$^{13}$C NMR offers simplified spectra with greater spectral dispersion, which are often best for preliminary information. Complete assignment of $^1$H NMR and $^{13}$C NMR resonances usually starts with the well-resolved anomeric H-1 or C-1 peak using 1-D NMR. The proton resonances can then be assigned sequentially using through-bond techniques: the H-2 by using 2-D time proportional phase incrementation/double quantum filtered/correlation spectroscopy (TPPI/DQF/COSY), then the H-3 using 2-D one-step delayed coherence transfer spectroscopy (RECSY) after eliminating the
DISACCHARIDE, OLIGOSACCHARIDE AND POLYSACCHARIDE ANALYSIS

H-2 signal, followed finally by the H-4 using 2-D time proportional phase incrementation/total correlation spectroscopy (TPPI/TOCSY) after eliminating both the H-2 and H-3 signals. All the protons associated with each carbohydrate residue can be identified using 2-D homonuclear Hartmann–Hahn spectroscopy (HOHAHA), or its close relation, total correlation spectroscopy (TOCSY), in D$_2$O. The cross-peaks for all ring protons H-2–H-6 (for hexoses) associated with the anomeric proton signal can be distinguished (Figure 10b), as the method utilizes a number of repetitive pulses that permit magnetization to flow freely from one proton to another at a rate determined by their $^{3}J$ coupling. TOF/COSY is particularly used to find groups of protons that couple, such as H-4/H-5e/H-5a in pentopyranoses and H-5/H-6/H-6' in hexopyranoses, but are the most difficult to assign by other correlation techniques. Linkage positions can be found by comparison between related oligosaccharides and noting the field shifts.$^{49}$

The anomeric conformation can often be determined directly from the chemical shift by comparison with known structures. It may be confirmed from the size of the anomeric $^{1}J_{C-1H}$ coupling constant, which is typically 170 Hz for axial hydrogen and 160 Hz if equatorial. The $^{3}J_{H-1H}$ coupling constants obey a Karplus relationship (Equation 12).

$$^{3}J = A \cos^2(\theta) - B \cos(\theta) + C$$  (12)

A, B and C are fitted parameters derived from a number of known trainer molecules. The cosine nature of Karplus curves means that it gives one to four possible angles every 360° for a given $^{3}J$ (Figure 11). Simple molecular modeling can usually make choice between these as often only one conformation is structurally reasonable. Karplus curves are not exact as other factors, such as bond lengths, bond angles and the nature and orientation of groups attached to the atoms, all have an effect. They can, however, generally give the torsion angles to within about 30° and allow the ring conformation (e.g. pyranose chair conformation $^4C_1$ or $^1C_4$) to be easily verified. Several Karplus parameters are available from different sources, which have been optimized on their

![Figure 10](image-url) **Figure 10** $^1$H NMR spectrum (600 MHz) of the arabinoxylan fragment $\alpha$-L-Ara–(1→2)$\beta$-D-Xyl–(1→4)$\beta$-D-Xyl–(1→4)-D-Xylp. (a) 1-D NMR showing the distinctive anomeric peaks, mainly as doublets. (b) 2-D HOHAHA NMR showing how off-diagonal assignments of each ring system can be made once the anomeric proton is assigned. Peaks on the diagonal are equivalent to the 1-D NMR spectrum. (Reproduced from Carbohydr. Res., 254, 245–255, © 1994 by permission from Elsevier Science.)

![Figure 11](image-url) **Figure 11** The Karplus relationship $^{3}J = A \cos^2(\theta) - B \cos(\theta) + C$. For the coupling constants involving the glycosidic linking torsions ($^{3}J_{COCH}$), A, B and C are 7.6, 1.7 and 1.6 Hz respectively.$^{58}$ It can be noted that for any experimental value of $^{3}J$ there may be up to four possible torsional angles (e.g. a $^{3}J_{COCH}$ of 6 Hz may be derived from a torsion of 28°, 131°, 229° or 332°).
own subset of structures or with the aid of quantum mechanical methods. As many compounds often have similar torsional angles for similar structures and a complete range of torsions (0–360°) are rarely available in the model compounds, these parameters may give very different results when away from their training angles. However, even if the parameters are very different, the equation generally gives good correspondence for the commonly found angles. The $^3J_{\text{H}_1-\text{H}_1}$ coupling constants are often able to confirm the molecular species and anomeric configurations present. For example, the anomeric configuration of glucopyranose and galactopyranose are easily observed, from the $^3J_{\text{H}_1-\text{H}_2}$ coupling constant, as the H-1 and H-2 protons of the beta anomers are trans-diaxial ($\sim$180°) giving large couplings whereas those in alpha anomers are gauche ($\sim$60°) with small couplings. Mannopyranose anomers are undecided by this method as both are gauche. D-xylose and D-glucose are characterized by large coupling constants for H-2, H-3, H-4 and H-5 (5a in xylose) arising from their mutually trans-diaxial orientations. Karplus curves giving the relationship of $^3J$ coupling constants to the H–C–C–H torsion are given in Haasnoot et al.

The power of NMR is most useful when it is used to determine the sequence, linkage positions and conformation of carbohydrates. This can only be attempted when there has been a full assignment of the $^1$H and $^{13}$C spectra and it is preferred that the carbohydrate has been enriched with the $^{13}$C isotope. Linkages can be determined from the $^3J_{\text{C}_1\text{H}_1-\text{H}_2}$ scalar coupling through and across glycosidic bonds using heteronuclear multiple bond correlation (HMBC) and from interglycosidic $^1$H NOE (nuclear Overhauser effect) effects using NOESY and ROESY (rotating frame nuclear Overhauser effect spectroscopy). This also allows the sequence to be determined from these through-space connectivities. However, with increasing size above about 20 glycosyl residues, it becomes increasingly difficult to delineate branch locations unambiguously. $^1$H NOE effects give those protons that are in close proximity (less than about 0.5 nm, the signal being inversely proportional to the sixth power of the inter-proton distance). They can be ambiguous particularly at branch points in certain conformations where protons, neighbouring the linkage site, may lie closer than the linkage protons although further apart in the primary structure. NOE effects are also difficult to interpret in the presence of significant internal molecular motion, due to positional averaging. Although NMR is difficult to apply to many polysaccharides, the presence of repeating units can be identified from the NMR of oligomers and quantified in polymers.

Linkage positions may also be discovered by determination of the position of the free hydroxyl groups, giving information similar to that obtained from methylation analysis (section 5.2), but nondestructively. $^1$H NMR spectra in H$_2$O ($\sim$10% D$_2$O) and D$_2$O are compared to identify the position(s) of the hydroxyl groups.

Hydroxyl proton signals are observed, downfield of anomeric protons, in H$_2$O at low temperature (e.g. $\sim$16°C in H$_2$O–perdeuterated acetone 4:1 v/v) when the pH is adjusted at 6.4 ± 0.2 to reduce the hydroxyl proton exchange with H$_2$O that is catalyzed above pH 7. Where the hydroxyl protons and their associated C–H aliphatic protons are coupled there is line broadening. If the line-width comparison fails to give the hydroxyl groups due to overlapping peaks then the COSY CH–OH cross-peaks may be used (in H$_2$O).

The biological roles of oligosaccharides and polysaccharides are related to their conformations. This mainly depends on the trans-glycidosidic torsional angles connecting the carbohydrate units (Scheme 4). Conformational analysis requires independent data for each independent torsion angle ($\phi$, $\psi$ and sometimes $\omega$) and, where a mixture of conformations exists, each relative population occupancy. These may be available from inter-residue proton NOE (e.g. between the anomeric proton and the proton on the linkage carbon, H–C$_1$–O–C$_n$–H) and the $^3J_{\text{COCH}}$, $^3J_{\text{COCC}}$, $^3J_{\text{CCCH}}$ and $^3J_{\text{COC}}$ coupling constants (Figure 11) but the cosine nature of the Karplus equation for $^3J$ coupling means modeling may be required. Whilst the conformation of rigid oligosaccharides can be directly derived from NOESY data, the upper and lower bounds of the possible distances from NOESY often enclose a large number of $\phi$, $\psi$ combinations. It is usual to combine NMR, molecular dynamics and random walk molecular mechanics (RAMM) in order to have confidence in the resulting conformation. The additional information available from molecular modeling is particularly useful for polysaccharides where these coupling constants may not be measurable. Modeling is also necessary in oligosaccharides where there are mixed conformational populations present. It should be noted that multiple conformations are often in fast equilibrium on the NMR timescale and NMR data are effectively time-averaged, which may give rise to unrealistic putative torsional angles.

A continuous probability distribution (CUPID) approach can analyze the rotamer populations from NMR spin–spin couplings and NOE enhancements. This gives results reported as typically ±30–40° for the dihedrals and ±0.2 for the probabilities. This method requires an amount of experimental data that is normally only available for rotations around carbon–carbon bonds such as the C5–C6 bond in hexopyranoses.

Solid state $^{13}$C NMR has been used on simple highly ordered polysaccharides, such as cellulose, but few detailed conclusions can be drawn.
Scheme 4 The torsions and possible coupling constants involved in the anomeric linkages in oligosaccharides and polysaccharides. (a) Torsions $\phi$ and $\psi$ are defined as the clockwise torsions $O_2 C_1 O_x C_n$, and $C_2 O_x C_n C_{n-1}$ respectively, where $r$, $a$, and $n$ represent ring, anomeric and structural number respectively. Alternative torsions are sometimes used as they are easier to determine experimentally; $\phi_H$ is $H_1 C_1 C_2 C_n$ (about $\phi + 120^{\circ}$), relative angles are not exact as the bond angles are not exactly tetrahedral) and $\psi_H$ is $C_x O_x C_n H_n$ (about $\psi + 120^{\circ}$). The relevant coupling constants are $J_{H_1 C_1 H_4}$ giving $\phi_H$, $J_{C_2 C_1 O_x C_n}$ giving $\psi_H$, $J_{C_2 C_1 O_x C_n}$ giving $\psi$ and $J_{C_1 H_4}$.

(b) An exocyclic link; the additional linking torsion $\omega$ is defined as the clockwise torsion $O_x C_n C_n C_{n-1}$. The relevant coupling constants are $J_{H_1 C_1 O_x}$ giving $\phi_H$, $J_{C_2 O_x C_n}$ giving $\psi_H$, $J_{C_2 O_x C_n}$ giving $\psi$, $J_{C_1 O_x H_4}$, $J_{C_1 O_x H_4}$, $J_{C_1 O_x C_n x}$, $J_{H_1 O_x C_n C_{n-1}}$ and $J_{H_2 O_x C_n C_{n-1}}$.

7.3 Infrared Spectroscopy

Fourier transform infrared (FTIR) is a rapid non-destructive and quantitative method for determining oligosaccharides and polysaccharides. Pure samples of the glycans and any interfering substances must be available for comparison. FTIR determines the whole spectrum at once, easily allowing a number of scans to be averaged to achieve high sensitivity and resolution. The complexity of the spectra means that it is not suitable for totally unknown mixtures where there may be interference from unknown materials.$^{(53)}$ Analysis is achieved from the absorbance at a number of differing wavelengths (~900–1200 cm$^{-1}$, e.g. the C–O stretching vibration) after comparison with the absorbance matrix obtained using the calibration materials.

Glycolipid Analysis

Ian M. Morrison
The Scottish Crop Research Institute, Invergowrie, UK

1 Introduction

Glycolipids are conjugated macromolecules that have a carbohydrate (oligosaccharide) component covalently bound to a lipid (diacylglycerol, ceramide, sterol or polyprenol) component. They are present both in procaryotes and eucaryotes but the carbohydrate components, as well as the lipid components, vary considerably between different animal, plant and microbial cells. The biological specificity of a glycolipid is due mainly to the carbohydrate structure. The amphipathic nature of glycolipids means that a single extraction scheme is impractical for all the different molecular species while special techniques are required to differentiate between the neutral glycolipids and acidic glycolipids (gangliosides). Thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC) are the major purification methods. Chemical methods are used to determine the carbohydrate and lipid profiles as well as the linkage analysis of both types of components and are used in conjunction with gas chromatography (GC), HPLC and TLC, sometimes coupled with mass spectroscopy (MS). Enzymatic methods can be used to determine the linkage sequence and anomeric configurations of the oligosaccharide structures and the same parameters are being determined by immunological methods with increasing frequency. Enzymatic methods are also used to establish the linkage analysis of the fatty acid in the diacylglycerol species. However, various MS and both 1H- and 13C-NMR (nuclear magnetic resonance) methods, but mostly the former, are now invariably used to confirm the full structural features of an unknown glycolipid. The type of MS method used, matrix-assisted laser desorption/ionization (MALDI), fast atom bombardment (FAB) or tandem mass spectrometry (MS/MS) will depend on the type of glycolipid.

1 INTRODUCTION

Glycoconjugate is the general term applied to macromolecules, usually biological, that have a carbohydrate component covalently bound to a noncarbohydrate component. The most widespread examples are glycoproteins and glycolipids. The same complex carbohydrate component can be associated with both examples. Glycolipids are found both in procaryotes and eucaryotes but the complex carbohydrate components, as well as the compounds that are considered to be the lipid components, vary considerably between the different animal, plant and microbial cells. Some simple glycolipids have been synthesized on an industrial scale and have commercial applications. The glyco components are complex oligosaccharide chains that may involve frequent branching. The carbohydrate components can also carry noncarbohydrate substituents such as acetate or sulfate groups linked by covalent chemical bonds. The lipid component is far more variable since many types of compound are considered as lipids. Diacylglycerol, ceramides (amides derived from a fatty acid and a sphingosine base), sterols and polyprenols are the most abundant. The biological specificity of a glycolipid is due more to the overall carbohydrate structure and influenced less by the lipid component.

In glycosphingolipids, glycerol is always in the sn-1 configuration and fatty acids are attached at C-1 (sn-1) and C-2 (sn-2) by ester bonds: it is unusual for the same
fatty acid to occupy both positions. The carbohydrate components, mostly frequently D-galactose or oligomers of this sugar residue, are always joined at C-3 (sn-3) by a glycosidic bond. A D-galactosyldiacylglyceride is shown in Figure 1(a). For the cerebrosides, the sphingosine base is normally unsaturated and its primary hydroxy group is involved in a glycosidic bond with the reducing end of the carbohydrate chain. The disialogangliosides G_{D1a} and G_{D1b} are shown in Figures 1(b) and 1(c). The cerebrosides can be subdivided into neutral cerebrosides and acidic cerebrosides (gangliosides). The neutral cerebrosides contain mainly neutral hexose and hexosamine residues while the gangliosides are characterized by the presence of the nine-carbon sugar, neuraminic acid, as well as the same sugars as are found in the neutral cerebrosides. Sulfatides are a special form of cerebrosides containing sulfate ester groups. As more sensitive detection methods are used, the range and complexity of carbohydrates present in glycolipids is increasing. D-Galactose has been found in the more unusual furanose form while residues of the acidic sugar, D-glucuronic acid, have also been detected. N-Acetylneuraminic acid is not the only sialic acid, N-glycolyl and N-O-disubstituted derivatives now being frequently detected, while other sugars, such as 3-deoxy-D-glycero-D-galacto-2-nonulosonic acid (KDN), are no longer considered to be rare. Molecular species can be found from the same source which have the same oligosaccharide chain along with the same sphingogine base but have different fatty acids present. The linkage between sterols and the carbohydrate chains are also through glycosidic bonds. The polyprenol-types are unique amongst the glycolipids as the link is via a phosphate bridge. Sterol- and polyprenol-types are not present in tissues and cells at high concentrations but the latter are widespread, being involved as transporters for the carbohydrate components of biologically active molecules.

2 EXTRACTION AND PURIFICATION

The very nature and definition of the name ‘glycolipid’ confirms that care must be taken during isolation and purification. Although carbohydrates are frequently, although not exclusively, water-soluble, the high concentration of hydroxy groups in their structures makes them hydrophilic. In contrast, lipids, by definition, are water-insoluble organic substances that can be extracted with nonpolar solvents. All glycolipids are, therefore, amphipathic. The combination of hydrophilic and hydrophobic regions in the same molecule accounts for many of their biological functions, especially in membranes, but does make their isolation and characterization more difficult.

The amphipathic nature means that the solvent system will generally require a polar and a nonpolar component. However, as the percentage of polar component to nonpolar component in a specific glycolipid (or lipoglycan) will depend on its composition and could approach either 0% or 100%, the ideal solvent system for any particular glycolipid needs to have similar polarity. No single solvent or mixture of solvents will, therefore, be capable of extracting all the glycolipids from a single biological sample.

Another paramount consideration when isolating glycolipids is the lability of the glycolipid in the extracting or purification solvent. The different covalent bonds in glycolipids have differentabilities under acidic and alkaline conditions.
conditions. Glycosidic bonds between the sugar residues in the oligosaccharide component as well as to the lipid component are relatively stable under alkaline conditions but are cleaved in acidic conditions, especially at elevated temperatures. All glycosidic bonds are not equally labile in acid and this factor can be used in structural analyses. Other components, particularly esters substituents, are less stable in alkaline conditions than acidic conditions. Unless some structural information has been previously obtained, both acidic and alkaline conditions should be avoided during extraction. Enzymic hydrolysis may also occur if precautions are not taken. Before biological samples are extracted, enzymes, if present, need to be inactivated. This is particularly relevant for the plant glycolipids since phospholipases and galactolipases may be present. Under these circumstances, a prior treatment with boiling propan-1-ol is recommended.\(^{(1)}\) Furthermore, care needs to be taken to prevent oxidation of unsaturated fatty acids as well as to minimize the co-extraction of plant pigments that can interfere with subsequent fractionation.

### 2.1 Extraction

Even though animal glycolipids are mainly glycosphingolipids and plant glycolipids are mainly monoglucosyl-diacylglycerols, most of the extraction procedures are based on the related methods of Folch et al.\(^{(2)}\) and Bligh and Dyer\(^{(3)}\) that were published in the late 1950s. Both procedures recommend that the fresh tissue is extracted with a chloroform–methanol mixture for up to 1 h at temperatures from 4°C to 25°C (sometimes up to 100°C is reported), with 4°C being preferred. Temperatures above ca. 25°C ought to be avoided unless labile constituents are known to be absent. Extraction periods as low as 3 min have been used. Periods of over 1 h are only recommended when fresh material is not available and lyophilized samples have to be used.

The recommended chloroform–methanol ratio depends on the proportions of lipid to carbohydrate in the glycolipid. Ratios from 1:2 through 1:1 to 2:1 have all been published and many authors cite sequential extractions with the different ratios. When a suspension of fresh tissue is used at a ratio of 3.75 volumes solvent to 1 volume tissue, the chloroform–methanol (1:2 v/v) mixture gives a one-phase extract containing chloroform–methanol–water (1:2:0.8 v/v/v). On adding more water and chloroform, two phases are produced with the glycolipids being found in the lower chloroform-rich phase and the nonlipid components being partitioned into the upper water-rich phase. The chloroform-rich phase is dried under vacuum and should be immediately fractionated or, if this is not practical, stored in a water-free form in chloroform–methanol (2:1) at −20°C. When an unknown source has been extracted, the water-rich phase should be examined to see if any highly polar glycolipids are present in that fraction. Clearly, even using chloroform:methanol mixtures, there is no single procedure that can be recommended for the extraction of all glycolipids from every biological source and, ideally, the method that is used requires optimization for the source being investigated.

Alternative solvent systems have been proposed. When chloroform–methanol (1:2) is used, 0.4 M sodium acetate can be used instead of water and is reported to give improved results when gangliosides are present.\(^{(4)}\) Another method, also reported to be particularly applicable to gangliosides, uses 0.01 M phosphate buffer in tetrahydrofuran.\(^{(5)}\) For the extraction of higher plant glycolipids, fresh tissue is fragmented in dry ice and homogenized in boiling propan-2-ol for 1–2 min. This procedure is recommended when degradative enzymes may be present. It is also reported to minimize peroxidation.

### 2.2 General Purification

In parallel with the extraction of glycolipids, no single method can be used to separate all the glycolipids in an extract from co-extracted contaminants. Each procedure must be tested for the particular fraction required. When the chloroform–methanol extracts obtained from either the Folch et al.\(^{(2)}\) or Bligh and Dyer\(^{(3)}\) procedures are separated into a two-phase system, the lower phase contains the neutral glycolipids, particularly those with short carbohydrate chains, as well as neutral lipids and phospholipids, while the upper phase contains not only the gangliosides and the neutral glycolipids with longer carbohydrate chains but also contaminating glycoproteins and glycopeptides. When gangliosides are present, the water-rich upper layer can be dialyzed against distilled water at 4°C for 2–3 days and the ganglioside fraction recovered by lyophilization of the retentate.

Many procedures have been published for general purification ranging from precipitation with propan-2-one to countercurrent distribution but the vast majority of applications use column chromatography. While diethylaminoethyl (DEAE) matrices have been used in the chromatographic methods, most procedures use silica gel when significant quantities of material are available. After applying the crude extract, such as the lower phase from a chloroform–methanol extract, to the column, neutral lipids and pigments are eluted by washing with chloroform and the glycolipids can be eluted by washing with chloroform–propan-2-one (1:1 v/v) or propan-2-one alone. Gradient elution can be used to provide an initial fractionation. Phospholipids, if present, can be recovered by subsequent elution with methanol–chloroform.
An adaptation of this procedure, initially described for gangliosides, was proposed by Williams and McCluer, who used solid phase extraction (SPE) columns packed with a matrix containing bonded octadecylsilyl (ODS) groups. These cartridge columns (Sep-Pak) are loaded with the ganglioside mixture present in the water-rich upper layer from a chloroform–methanol extract. Washing with water, under slight either positive or negative pressure, removes the ions, and the gangliosides are removed by washing with methanol or chloroform–methanol.

As well as ODS-bonded matrices, cartridges are now available with a range of matrices such as silica gel as well as both cation- and anion-exchange materials. Being produced under standard commercial conditions, the reproducibility between columns can almost be guaranteed. With care and suitable washing, the cartridges can be used a number of times. The use of SPE in all aspects of lipid analysis has been reviewed. Gel permeation matrices have also been used for general purification procedures. The water-compatible Sephadex G-25 and the matrix designed for nonaqueous solvents, Sephadex LH-20, have both been used.

### 2.3 Separation into Neutral Glycolipid and Acidic Glycolipid (Ganglioside) Fractions

The ability of the acidic sugar residue(s) in the ganglioside to bind to DEAE-groups attached to various supports is the main method and a procedure using DEAE–Sephadex is typical. The authors recommend that the acetate form of the gel and the column be prewashed with chloroform–methanol–water (15:30:4 v/v/v) before loading the sample in the same solvent mixture. The neutral glycolipids are washed off using the same solvent and the gangliosides are then eluted with 0.8 M sodium acetate in methanol.

Since individual gangliosides may contain more than one acidic (sialic acid) residue, DEAE-matrices can also be used to fractionate monosialo-, disialo- and trisialoganglioside mixtures. This procedure recommends that the crude ganglioside mixture is dispersed in chloroform–methanol (1:1) and mixed with the acetate form of DEAE–Sephadex A-25 with shaking. The suspension is diluted with methanol–water (15:4 v/v) before being packed into the column. The neutral lipids are eluted with chloroform–methanol–water (15:30:4 v/v/v) and neutral glycolipids with methanol. The gangliosides can then be fractionated using a concave gradient of 0–0.45 M ammonium acetate in methanol. Ganglioside species containing a single sialic acid residue are eluted first and those with 3–4 residues require the higher molarity of ammonium acetate.

### 2.4 Separation of Glycolipid Mixtures

#### 2.4.1 Thin-layer Chromatographic Methods

TLC procedures for lipid separations have been reviewed and their applications in glycolipid analyses are numerous. Using the term high-performance thin-layer chromatography (HPTLC) as a special form of this technique highlights the availability and reproducible quality of very fine grade silica gels. It has many advantages over HPLC. The fineness results in superior resolution. These grades of silica gel cannot be used in HPLC due to the pressure requirements, while very sensitive but destructive or corrosive reagents can be used for detection purposes. The plates are readily impregnated with additives such as Ag⁺ or borate ions that enhance the separation of specific components such as unsaturated or vicinal dihydroxy-containing compounds.

Neutral solvent systems, such as chloroform–methanol–water (65:25:4 v/v/v), are recommended for neutral glycolipids. Derivatization of the glycolipid by, for example, acetylation is not reported to give any improvement to the separation. Any acceptable reagent that can detect nonreducing sugars, such as orcinol/H₄SO₄, can be used to visualize the components. When carrying out preparative TLC, care should be taken to prevent the plates from drying out: quantitative recovery is not achieved even when ultrasonic treatment is used.

The best methods for the separation of gangliosides are also based on silica gel and detection is achieved with the resorcinol/HCl spray reagent. However, a basic solvent system (e.g. chloroform–methanol–water–ammonia (60:35:7:1 v/v/v/v)), or one containing Ca²⁺ ions (e.g. chloroform–methanol–0.2% aqueous CaCl₂ (60:40:9 v/v/v)) gives optimum separations in a one-dimensional system. Two-dimensional (2-D)/TLC is frequently used for analyzing glycolipid mixtures, particularly when only small quantities of material are available (see, for example, Sonnino et al.). For neutral glycolipids, chloroform–methanol–0.2% CaCl₂ (60:35:8 v/v/v) has been recommended for both dimensions while for ganglioside molecular species, chloroform–methanol–0.2% CaCl₂ (55:45:10 v/v/v) has been recommended for the first dimension and propan-1-ol–water–25% NH₄OH (75:25:5 v/v/v) for the second.

A simple and quantitative purification procedure, based on TLC, is termed TLC blotting. After 2-D HPTLC, the separated components are treated with primuline and visualized under ultraviolet (UV) light. The bands are marked with a colored drawing pencil then transferred, by TLC blotting, onto a polyvinylidene difluoride (PVDF) membrane. The major advantage is the yield and purity of the products. Direct extraction of an HPTLC plate rarely recovers more than 50% of the
lipid component while yields of 80–90% are regularly achieved using the PVDF membrane. Another benefit of PVDF membrane technology is the development of more sensitive detection methods. When the glycolipids on the PVDF membrane are mildly oxidized, they can be conjugated with streptavidin–horseradish peroxidase and, using enhanced chemiluminescence, are clearly visible at a concentration factor of 10 lower than detected by the orcinol reagent. The method can be generally applied to the use of a specific antibody for detection and, since the staining procedure is nondestructive, the glycolipids can still be used for further molecular analyses.

A further adaptation of 2-D TLC, especially applicable to gangliosides, is termed TLC mapping. The glycolipid mixture is first chromatographed in one dimension on a narrow NH₂-silica gel HPTLC strip using chloroform–methanol–1% diethylamine (50:47:15 v/v/v). This strip is then clamped to a 2-D TLC plate and developed with chloroform–methanol–25% NH₄OH (4:10:6 v/v/v). The partially separated glycolipids are transferred from the strip to the plate and chromatographed in the first dimension in a simultaneous process. The plate can then be run in the second dimension with chloroform–methanol–0.2% CaCl₂ as above. The method allows the determination of membrane constituents, particularly those that are present at low concentrations. A typical TLC map of the gangliosides from rat brain is shown in Figure 2.

2.4.2 High-Performance Liquid Chromatographic Methods

Because of the expansion in the use of HPTLC (see section 2.4.1), the applications using HPLC have not expanded as greatly as anticipated a decade ago. Columns that can compete with HPTLC by incorporating Ag⁺ and borate ions have been developed and gradient elution at different temperatures is easy to perform. However, the pressure limits on the fineness of the silica gel that can be used as well as the detection limits are major obstacles. The IR detector is too insensitive while UV detection at 190–210 nm is nonspecific.

For native glycolipids, HPLC on silica is used for the separation of lipid classes while reversed-phase or bonded columns are used for the separation of molecular species. Native neutral glycolipids can be separated on porous silica using a gradient involving propan-2-ol–hexane–water. For native gangliosides, silica gel and DEAE-linked glass beads have been used but the preferred method uses Lichrosorb-NH₂ or µ-Bondapak-NH₂ columns. Molecular species within mono-, di- and trisialo-ganglioside fractions can be separated on a single run.

The introduction through chemical modification of the more UV-sensitive benzoyl or p-nitrobenzoyl groups into the glycolipids has greatly reduced the sensitivity problem. These groups also change the polarity of the glycolipid and allow a widely different set of solvent systems to be used. While the p-nitrobenzoyl derivatives are more UV-sensitive, the benzoyl derivatives usually give a better separation. The method used to prepare the derivatives is also important and depends on whether the native glycolipid needs to be recovered intact. Benzoyl chloride in pyridine gives a fully substituted product but treatment with benzoic anhydride and 4-dimethylaminopyridine as catalyst results only in O-benzoylation. The fully benzoylated derivative gives better separations than the O-benzoylated product. However, attempts to recover the

\caption{2-D thin layer chromatogram (TLC map) of the ganglioside mixture isolated from rat brain: (a) to (d) refer to the mono- to tetrasialoganglioside fractions, respectively, and (e) refers to an, as yet, unidentified ganglioside fraction. (Reprinted with permission of Academic Press, New York from Anal. Biochem., 227, 195–200 (1995).) }
\end{figure}
native glycolipid with mild alkali only remove \(O\)-benzoyl groups: the \(N\)-benzoyl groups on either the sphingosine base or any amino sugars are stable.\(^{20}\)

More recent developments with moving wire flame ionization detectors offer increased sensitivity for native glycolipids and the evaporative light-scattering detector is also a sensitive detection method when separating lipid classes, including glycolipids. This latter technique has been used to separate the nine phospho- and glycolipid classes present in plant membranes.\(^{21}\)

2.4.3 Supercritical Fluid Chromatographic Methods

SFC is a relatively new technique that has been adapted by Reinhold et al.\(^{22}\) for the separation of glycolipids. In general, thermally labile and nonvolatile compounds can be analyzed at lower temperatures than are possible with GC while the use of a flame ionization detector gives the method increased sensitivity over HPLC. A permethylated ganglioside mixture containing the mono-, di- and trisialogangliosides, \(G_{M1}, G_{D1a,b}\) and \(G_{T1b}\), has been separated on an SB-phenyl-5\({}^{23}\) column at \(120^\circ\text{C}\) using \(\text{CO}_2\) as the supercritical fluid. The separation is shown in Figure 3. Possibly the main strength of the method is the ability to couple directly to a mass spectrometer and use the \(\text{CO}_2\) along with \(\text{NH}_3\) as chemical ionization reagent (see section 5.1).

3 CHEMICAL METHODS OF ANALYSIS

3.1 Composition of Glycolipids

3.1.1 Carbohydrate Profiles

The glycosidic bonds present in any polymeric carbohydrate, including glycolipids, are hydrolyzed under acidic conditions. Hydrolysis is most efficient when carried out under homogeneous conditions but the amphipathic nature of all glycolipids means that a single process cannot be recommended for all glycolipids. Glycolipids with a high proportion of carbohydrate residues are more likely to be soluble in an aqueous acidic solution while those with a small proportion of carbohydrate residues require

![Figure 3 Supercritical fluid chromatography (SFC) mass spectrometry of the permethylated gangliosides \(G_{M1}, G_{D1a,b}\) and \(G_{T1b}\) from bovine brain using \(\text{NH}_3/\text{CO}_2\) as CI reagent gas.\(^{22}\) (Reprinted with permission of Academic Press, New York from Anal. Biochem., 193, 24–34 (1991).)
a less polar solvent such as an acidic water–methanol mixture.

Furthermore, the glycosidic bonds of each type of carbohydrate residue found in glycolipids are not hydrolyzed at the same rate. In general, those involving amino sugars (e.g., galactosamine and its naturally occurring N-acetyl derivative) are relatively stable and require high concentrations of H\(^+\) ions (ca. 0.3 M) for longer periods of time and at elevated temperatures. Glycosidic bonds involving the pyranose forms of most hexoses (e.g., gluco- and galactopyranose) are less stable. They still require high concentrations of H\(^+\) ions (ca. 0.3 M) at elevated temperatures but not for such long periods. The precise conditions will depend on the sugar residue, its ring size (pyranose or furanose), its anomic configuration (α or β) and the position of linkage to the aglycone. The aglycone can be another sugar residue, the sphingosine base, glycerol or whatever the lipid is. The most labile sugar residues found in glycolipids are the sialic acids or any furanosyl forms of sugars. In particular, galactofuranosyl groups have been identified in glycolipids from many microbiological sources.

In practice, it is not possible simply to use the conditions required to hydrolyze the most stable glycosidic bond. The reducing sugars released by hydrolysis are themselves unstable when exposed for prolonged periods to acidic conditions at elevated temperatures. The sialic acids present in gangliosides are particularly unstable. It must also be remembered that noncarbohydrate substituents attached to sugar residues, such as the N-acetyl groups on amino sugars and acetyl or sulfate groups present on neutral sugar residues, will also be hydrolyzed under acidic conditions. Preliminary analyses may be necessary to select the optimum conditions for a particular glycolipid.

Hydrolysis procedures involving H\(_2\)SO\(_4\), HCl and trifluoroacetic acid have been recommended but one using glacial acetic acid–0.15 M H\(_2\)SO\(_4\) (9 : 1) at 80 °C for 6 h is frequently used. After neutralization of the H\(^+\) or removal via an ion-exchange resin, the dried hydrolysate is reduced with borohydride to the corresponding alditol. Borodeuteride is used if subsequent analysis will include mass spectrometry. This procedure simplifies the chromatography by converting the α/β anomers of the pyranose/furanose forms into a single product. The alditol is then acetylated with acetic anhydride and products analyzed by GC or GC/MS. Many variations have been published but the general procedure of Watanabe et al.\(^{26}\) is recommended. Improved gas chromatographic procedures have been published (see, for example, Blakeney et al.)\(^{27}\) and milder acetylation conditions involving the use of 1-methylimidazole as catalyst\(^{28}\) have been recommended. These hydrolysis conditions are necessary to release amino sugars but sialic acid residues are destroyed.

Methanolysis is recommended for gangliosides but can be used for other glycolipids. The glycolipid is treated with 1.0 M methanolic HCl at 85 °C for 18 h in a sealed tube. This procedure hydrolyzes the glycosidic bonds but simultaneously protects the vulnerable hemiacetal group by creating the methyl glycosides. After neutralization with Ag\(_2\)CO\(_3\) or ion-exchange resin, and re-N-acetylation if amino sugars are present, the trimethylsilyl (TMS) derivatives of the methyl glycosides are prepared by conventional methods\(^{29}\) and analyzed by GC.\(^{30}\) The methanolysis procedure is acceptable for terminaly-linked sialic acids but the conditions need to be made less severe when internal sialic acid residues are present. Since sialic (neuraminic) acid residues can be present carrying either N-acetyl or N-glycolyl substituents, as well as some residues being disubstituted, specific procedures involving GC, HPLC or colorimetric analyses have been reviewed.\(^{31}\)

An interesting scheme has been proposed by Wiesner and Sweeley\(^{32}\) where the glycolipid is methanolyzed with 0.75 M HCl in methanol. Using a glycolipid that contained a sialic acid residue and an amino sugar as well as neutral sugars, methanolysis was complete in 2 h at 110 °C. Instead of the TMS derivative, peracetylation introduced the more stable acetyl group. In contrast to other procedures, the individual sugar residues, the fatty acids and the sphingosine moieties could all be determined by a single GC separation in 45 min. This procedure is likely to be universally adopted.

The carbohydrate profiles from the plant monoglycosyldiacylglycerols are now known to be more complex than originally reported. In addition to the three carbohydrate moieties, β-D-galactopyranosyl, 6′-O-α-D-galactopyranosyl-β-D-galactopyranosyl and sulfoquinovosyl frequently cited, higher homologues of the second have been found as well as all α/β linked galactosyl oligosaccharides.

### 3.1.2 Fatty Acid Profiles

The release of the individual fatty acids present in glycolipids is subject to the same general problems that were discussed for the carbohydrate profiles (see section 3.1.1). A purely aqueous hydrolysis is not practical and the most generally recommended method involves heating a methanol–H\(_2\)O–conc HCl (29 : 4 : 3) mixture at 80 °C for 18 h in a sealed tube under N\(_2\). After extraction of the fatty acids (and some methyl esters), all the fatty acids are esterified with 1.5 M methanolic HCl and determined by capillary GC on a BP1 or BPX70 column.\(^{33}\)

Methyl esters have been prepared using different reagents such as BF\(_3\)/methanol, AlCl\(_3\)/methanol and diazomethane. Pentfluorobenzyl esters have significant advantages if the more-sensitive electron capture detector is used for the GC whereas propan-2-yl esters give better
resolution for the different trans isomers. If the analysis involves GC/MS, the introduction of an N-containing ester group, such as a picolinyl or pyrrolidide group, is preferred for the MS.\(^{(34)}\) When hydroxy fatty acids are present, the peak width of these acids is increased and tailing also occurs. The quality of the chromatograms and, therefore, the accuracy of quantification are improved by trimethylsilylating the hydroxy groups of the fatty acid methyl esters. The retention times are also reduced.

Reversed-phase HPLC offers an alternative strategy for the analysis of individual fatty acids and the topic has been reviewed.\(^{(35)}\) The methyl esters are not sufficiently sensitive for most HPLC detection systems but the introduction of a phenacyl group allows more sensitive detection in the UV while introduction of the 4-bromomethyl-7-methoxycoumarin group allows detection by fluorescence. \(\text{Ag}^+\) ion chromatography has special benefits when double bonds are present and the presence of borate ions assists the separation of any dihydroxy acids.

### 3.1.3 Other Components

The sphingosine bases are released from glycosphingolipids by treatment with methanol–\(\text{H}_2\text{O–conc HCl}\) (29 : 4 : 3 v/v/v) as described above for the release of fatty acids (see section 3.1.2). They remain in the acidic aqueous phase when the fatty acids and esters are extracted with petroleum ether but can then be extracted with diethyl ether when the pH is raised to \(>8\). They are then determined by GC of their TMS derivatives\(^{(36)}\) but the scheme proposed by Wiesner and Sweeley\(^{(32)}\) for carbohydrate profiles (see section 3.1.1) can be used to determine the sphingosine bases simultaneously.

Sterols are released and isolated by a similar method to the sphingosine bases. They can be analyzed directly by GC but the acetate derivatives give improved resolution and analysis times. Glycerol is quantitatively released by GC but the acetate derivatives give improved resolution for the different trans isomers. If the analysis involves GC/MS, the introduction of an N-containing ester group, such as a picolinyl or pyrrolidide group, is preferred for the MS.\(^{(34)}\) When hydroxy fatty acids are present, the peak width of these acids is increased and tailing also occurs. The quality of the chromatograms and, therefore, the accuracy of quantification are improved by trimethylsilylating the hydroxy groups of the fatty acid methyl esters. The retention times are also reduced.

Reversed-phase HPLC offers an alternative strategy for the analysis of individual fatty acids and the topic has been reviewed.\(^{(35)}\) The methyl esters are not sufficiently sensitive for most HPLC detection systems but the introduction of a phenacyl group allows more sensitive detection in the UV while introduction of the 4-bromomethyl-7-methoxycoumarin group allows detection by fluorescence. \(\text{Ag}^+\) ion chromatography has special benefits when double bonds are present and the presence of borate ions assists the separation of any dihydroxy acids.

### 3.2 Linkage Analysis of Carbohydrate Chains

Linkage analysis of the carbohydrate chain in a glycolipid will not give an unambiguous structure of the carbohydrate component of a glycolipid. It will give an indication of the relative position of each sugar residue present and, by analogy with known structures, the unknown structure may be derived. All nonreducing terminal residues are identified as well as main chain residues that have a single substitution point and branch points that are doubly substituted. The pattern is mainly determined after permethylation of the glycolipid (or the oligosaccharide derived from it). The product is then hydrolyzed to the partially methylated sugars, reduced, acetylated and the products determined by GC or GC/MS. The essential requirement is that every hydroxy group must be substituted. This may not always occur for native glycolipids; under these circumstances, it is preferable to release the oligosaccharide chain prior to methylation.

#### 3.2.1 Isolation of Oligosaccharide Chains

A number of procedures have been used to isolate intact oligosaccharide chains from native glycolipids. Most rely on the presence of a double bond in most naturally occurring sphingosine bases. In the procedure using osmium tetroxide/periodic acid,\(^{(38)}\) the glycolipid is first acetylated before the oxidizing agents break the double bond in the sphingosine base. The rump of the base is finally removed from the oligosaccharide chain with sodium methoxide, which also removes the acetyl-protecting groups to leave the intact oligosaccharide. Recoveries are not complete: the recovery from a ceramide with three sugar residues was 70% but ~50% from a ceramide with two sugar residues. Ozone can also be used to split the unsaturated bond in the sphingosine base without the need to acetylate and the aldehydic rump is removed with aqueous base.

Trifluoroacetylation results in different products depending on the ratio of trifluoroacetic acid to trifluoroacetic anhydride.\(^{(39)}\) O-trifluoroacetylation is complete and amino functions are all N-trifluoroacetylated. N-Acetyl groups undergo transamidation to N-trifluoroacetylated groups but sialic acid residues are hydrolyzed from the gangliosides. If an unsaturated sphingosine base is present, the oligosaccharide is released, although yields are not quantitative. A 1 : 1 ratio is recommended for monoglycosylerceramides, giving a better yield of glucose or galactose, while a 1 : 50 ratio gave a better yield with a triglycosylerceramide.

#### 3.2.2 Methylation Procedures

The ability to methylate oligosaccharide chains fully in intact glycolipids or those released from glycolipids (see section 3.2.1) with essentially no degradation is based on the work of Hakomori.\(^{(40)}\) The method uses the methysulfinyl anion, generated from NaH and dimethylsulfoxide (DMSO), to ionize all the hydroxy groups on a carbohydrate and these are converted to methyl ethers by reacting with iodomethane. Over the years, many modifications have been suggested, including a cleaner preparation of the methysulfinyl anion from KH or potassium \(\text{r-butoxide}\). The hazardous nature of the preparation of these carbanions, particularly that...
prepared from KH, needs to be stressed. Although relatively stable as dispersions in mineral oil, pure hydrides are extremely reactive and must only be used in small quantities and with great care.

As for the carbohydrate profiles (see section 3.1.1), the composition of the carbohydrate component of the glycolipid, and therefore the stability of the individual glycosidic linkages, will affect the hydrolysis conditions employed to depolymerize the permethylated glycolipid. If amino sugars are present, stronger hydrolysis conditions are needed such as glacial acetic acid–5 M H$_2$SO$_4$ (19 : 1 v/v) at 80°C for 18 h. When only neutral sugars (or sialic acids) are present, permethylated glycolipids can be depolymerized by heating with 95% formic acid at 100°C for 2 h. Conventional methods are used to clean up the products. 2 M Trifluoroacetic acid at 121°C for 1 h is a convenient alternative when only neutral sugars are present: the acid can be conveniently removed in a stream of N$_2$.

Most applications use GC or GC/MS to identify and quantify the products and the alditol acetate method is employed to depolymerize the permethylated glycolipid. If amino sugars are present, stronger hydrolysis conditions are needed such as glacial acetic acid–5 M H$_2$SO$_4$ (19 : 1 v/v) at 80°C for 18 h. When only neutral sugars (or sialic acids) are present, permethylated glycolipids can be depolymerized by heating with 95% formic acid at 100°C for 2 h. Conventional methods are used to clean up the products. 2 M Trifluoroacetic acid at 121°C for 1 h is a convenient alternative when only neutral sugars are present: the acid can be conveniently removed in a stream of N$_2$.

Most applications use GC or GC/MS to identify and quantify the products and the alditol acetate method is that of choice (see section 3.1.1). The procedure has been reviewed.

A more recent advance has been selectively to hydrolyze the permethylated glycolipid at a labile bond. In this procedure, the oligosaccharides released are reduced, the generated hydroxy groups are converted to ethyl ethers (as for methylation) and products separated by HPLC. GC/MS or MS alone allows structural features of the oligosaccharides to be determined.

### 3.3 Anomeric Configuration of Carbohydrate Residues

There are no chemical methods currently available that will definitively identify the anomeric configurations of the carbohydrate residues in a glycolipid, and biochemical and/or physical methods (see sections 4 and 5) are far more reliable.

### 3.4 Linkage Analysis of Fatty Acids

In plant glycolipids, as well as variations in the structures of the carbohydrate components (see section 3.1.1), the fatty acids esterified to the glycerol backbone can vary. The structure, isolation and analysis of plant glycolipids have been reviewed. Irrespective of the nature of the carbohydrate, it is always attached to C-3 of glycerol in the sn configuration. The fatty acids, therefore, are attached to C-1 and C-2 and the overall pattern as well as the distribution of individual fatty acids in each molecular species is biologically and industrially important.

Lipases have been isolated from a number of sources that are regioselective for the sn-1 ester group and so are capable of releasing the intact acyl group from C-1 (sn-1) of all glycolipids except those containing sulfoquinovosyl groups. This fatty acid can be directly determined (see section 3.1.2) and the lysoglycerolipid, which still contains the acyl group attached to C-2 (sn-2) can then be hydrolyzed and this fatty acid also determined. Only one extracellular lipase, isolated from Rhizopus arrhizus, is capable of carrying out the above reaction with the sulfoquinovosyl-containing glycolipids.

---

### 4 BIOCHEMICAL METHODS OF ANALYSIS

#### 4.1 Linkage Analysis and Anomeric Configuration via Specific Glycosidases

Exo-glycosidases act by cleaving the glycosidic bond of that specific glycoside when present in a nonreducing terminal position. The procedure is best explained by referring to an actual example. A pentaglycosylceramide of the globo series has the structure shown in Figure 4. The glycosidic bond involving the nonreducing terminal α-N-acetyl-D-galactosaminosyl residue is specifically removed by the action of the purified α-N-acetyl-D-galactosaminidase from hog liver. In common with most glycolipid methods, a general protocol, applicable to all possible situations, cannot be given but some recommendations can still be made. First, the purity of the enzyme is paramount. Even traces of other glycosidase activities will yield erroneous results. The amphipathic nature of

---

**Figure 4** Structure of the pentaglycosylceramide of the globo series showing how the sequential action of an α-N-acetyl-D-galactosaminidase, a β-N-acetyl-D-galactosaminidase, an α-D-galactosidase, a β-D-galactosidase and a β-D-glucosidase are required to determine the oligosaccharide sequence and anomeric configurations.
glycolipids means that a detergent such as sodium taurocholate is usually incorporated in the reaction buffer. The method is not just applicable to any nonreducing terminal residues. Addition of chloroform–methanol to the aqueous solution of reaction products gives a two-phase system with the released sugar residue in the upper aqueous phase and the remainder of the glycolipid, now containing one fewer sugar residue, in the lower phase. The released sugar residue is recovered and determined (see section 3.1.1) and the new glycolipid can be recovered and treated with another exo-glycosidase.

The method does have to be treated with some caution. If the internal α-D-galactosyl residue had been another α-N-acetyl-D-galactosaminosyl residue, its glycosidic bond would not have been susceptible to the exo-glycosidase. However, if the internal β-N-acetyl-D-galactosaminosyl residue had been another α-N-acetyl-D-galactosaminosyl residue, both α-N-acetyl-D-galactosaminosyl residues would have been hydrolyzed at the same time. The method is straightforward but, for an unknown glycolipid, can be time-consuming. The method, therefore, allows the carbohydrate sequence to be determined as well as the anomeric configuration of the different sugar residues. It cannot give any reliable information on the position of linkage to the next sugar residue in the sequence. Highly purified exo-glycosidases are now commercially available for each of the anomeric configurations of most of the sugar residues found in neutral glycolipids.

The gangliosides pose a greater problem. Sialidases have been isolated and purified but their activity is reported to be dependent on the environment of each sialic acid as well as the reaction medium. The presence of N-glycolyl and disubstituted neuraminic acids, as well as the more common N-acetyl residues, affects the specificity.

4.2 Linkage Analysis via Immunological Methods

The use of immunological methods has greatly expanded and the technique owes much to the work of Hako-mori and Young.⁵⁴ One of the earliest reports⁵⁵ used monoclonal antibodies that had been raised against the terminal oligosaccharide sequences β-D-Galp-(1→4)-β-D-GlcNAc-(1→R) and α-L-Fucp(1→2)-β-D-Galp-(1→4)-β-D-GlcNAc-(1→R). Glycolipids carrying these sequences could be differentiated from each other. Because of their specificity, monoclonal antibodies are able to detect the individual sugar residue and its anomeric configuration as well as the linkage arrangement within a relatively short segment of the nonreducing terminus of the oligosaccharide component. As more specific monoclonal antibodies are produced, the range of sequences that can be characterized will increase. Furthermore, the combination of detection through the use of antibodies coupled with TLC and TLC blotting onto PVDF membranes leads to a level of detection that would not have been considered feasible even in the late 1980s.

As the general methods proposed are very similar to the original ones, two more recent examples are cited to show what is possible. Using monoclonal antibodies to type 1 precursor, H-type 1, Le-a and Le-b epitopes, small quantities of Le-b blood group glycolipids were detected in a Lewis negative individual.⁶⁵ Previous studies by Marcus’s group had produced seven murine monoclonal antibodies that were active against Le-x. Using a phage display library, two novel antibodies have been produced whose affinities are 10² higher than the originals.⁶⁶ As well as binding to Le-x, one of the new antibodies will bind to sialyl Le-x while the other will also bind to neolactosylceramide.

5 PHYSICAL METHODS OF ANALYSIS

5.1 Mass Spectroscopy

Of all the analytical methods and techniques that have been applied to the analysis of glycolipids, those involving MS have made the greatest impact since the late 1980s. Indeed, it is now very rare to see a research paper on glycolipids without some MS-related analysis or characterization. The theory of the different MS techniques, electrospray ionization (ESI), MALDI, FAB and so on, will not be addressed: there are many reviews currently available. This section will try to summarize the relevant techniques that can be applied to the analysis of glycolipids, giving as many examples from as wide a range of glycolipid types as possible.

One of the major advantages of MS is the very small sample size that can be analyzed. Another major asset is the ability to couple MS to other analytical instruments. GC/MS has been available for many years. The interface between MS and SFC is straightforward and LC/MS (liquid chromatography MS) is now in routine use. The earlier unreliability of the coupling interface between the two systems has largely been solved. Even the analysis of spots or bands on HPTLC is now compatible with MS largely through the use of blotting onto PVDF membranes (see section 2.4.1). Special mention will be made of combined methods such as collision induced dissociation FAB/(CID)/MS/MS (see later).

5.1.1 Matrix-assisted Laser Desorption/Ionization Methods

The technique of MALDI, as applied to oligosaccharides and glycoconjugates, has been reviewed⁶⁸ while specific results for glycosphingolipids⁶⁹ have been published.
Glycolipids, as well as the oligosaccharides derived from them, give mainly \([M + Na]^+\) ions which is in contrast to glycoproteins where \([M + H]^+\) ions are more abundant. Resolution is generally superior with ion cyclotron resonance and magnetic sector instruments over time-of-flight (TOF) instruments. Neutral glycolipids are able to produce strong spectra from a number of different matrices but the gangliosides do undergo extensive fragmentation due to the destruction of the sialic acid residues.

The best matrices for neutral glycosphingolipids are 2,5-dihydroxybenzoic acid (2,5-DHB), \(a\)-cyano-4-hydroxycinnamic acid and esculetin, particularly in the positive-ion mode. When \(N\)-acyethylhexosaminyl residues were not present in the glycolipid and 2,5-DHB was used as matrix, fragmentation occurred between the carbohydrate and lipid revealing the structure of these components. With other matrices, loss of the acylamide from the ceramide was dominant and gave the distribution of C atoms between the acyl and sphingosyl groups. In contrast, when \(N\)-acyethylhexosaminyl residues were present, fragmentation was not as specific but did allow much structural information to be gathered. For the gangliosides, loss of CO\(_2\) and sialic acids both occurred while other fragment ions, derived from glycosidic cleavage, identified the carbohydrate sequence. The low-resolution MALDI spectra of the ganglioside GM\(_2\), obtained with the matrix, was confirmed by the negative ions, \([M - Na]^-\) ions. In the high-energy CID spectra, \([M + Na - H]^+\) ions while bis-sulfated species gave \([M + Na - H - Na]^2+\) ions. In the high-energy CID spectra, only ions containing sulfate esters were detected, with major differences depending whether the sulfate group was attached to a nonreducing terminal residue or was present on an inner hexose residue. The low-energy CID spectra were very simple with only one or two product ions, specific for each sulfated glycolipid, being detected. Combining the data, oligosaccharide structures differing in location and number of sulfate esters could be distinguished from each other.

5.1.2 Fast Atom Bombardment Methods

The analysis of glycolipids has been simplified by the use of soft ionization techniques such as FAB. The structural characterization of the sulfogluco-syl diacylglycerols from a cyanobacterium, dissolved in chloroform–methanol, in both positive ion (containing \(m\)-nitrobenzyl alcohol) and negative ion (containing trimethylamine) modes is shown in Figure 6.\(^{52}\) The former gives \([M - H + 2Na]^+\) ions and the two main peaks at \(m/z\) 865 and 839 correspond to a total fatty acid composition of 34:1 and 32:0, respectively. The fatty acid profile is confirmed by the negative ions, \([M - H]^-\), at 819 and 793.

Another specific technique is the direct negative ion FAB/MS of glycosphingolipids separated on TLC plates.\(^{53}\) The plates are moved within the ion source by a motor-driven probe. The technique has been optimized on neutral glycolipids containing five- and seven-sugar residues but has also been able to give a sequence determination for a highly branched eight-sugar glycolipid. As well as information on the oligosaccharide, molecular species with different ceramide compositions could also be detected.

5.1.3 Electrospray Ionization Mass Spectrometry

Electrospray ionization mass spectrometry (ESIMS) is another type of soft ionization that has been shown to give molecularly related ions with high sensitivity and accuracy. It is reported to be very accommodating for polysialogangliosides and the spectrum of a tetrasialo-ganglioside has been published.\(^{54}\) There are references to the technique alone but it is likely to be more useful in conjunction with other secondary techniques such as MS/MS/CID/MS/MS.

5.1.4 Liquid Secondary Ion Mass Spectrometry

This technique has been used for sulfated gangliosides.\(^{55}\) From the normal negative liquid secondary ion mass spectrometry (LSIMS) spectra, monosulfated species gave \([M - H]^+\) ions while bis-sulfated species gave \([M + Na - H]^+\) ions. In the high-energy CID spectra, only ions containing sulfate esters were detected, with major differences depending whether the sulfate group was attached to a nonreducing terminal residue or was present on an inner hexose residue. The low-energy CID spectra were very simple with only one or two product ions, specific for each sulfated glycolipid, being detected. Combining the data, oligosaccharide structures differing in location and number of sulfate esters could be distinguished from each other.
5.1.5 Tandem Mass Spectrometry

MS/MS, as its name implies, employs two stages of mass analysis. The general aim is to produce particular, often molecular, ions in one system and then to fragment these ions in another system. The fragment ions produced in the second system will be characteristic of the compound. In theory, two isomeric compounds could produce molecular ions of similar mass but should be differentiated by the fragmentation pattern. The technique, as applied to glycolipids, has been reviewed and some examples are given below.

The sulfoquinovosyldiacylglycerols, discussed under FAB (see section 5.1.2), had a major molecular ion \([M - H + 2Na]^+\) at \(m/z\) 865 in the positive-ion FAB spectrum. The high mass region, obtained from the CID breakdown of this ion (see Figure 7: an MS/MS system), had ions at \(m/z\) 739, 725, 711, 697, 683, 669 and 655 which are characteristic of an 18:1 unsaturated fatty acid group, namely oleic acid, at C-1. The ions at

Dabrowski, Hanfland and Egge reviewed the earlier applications. Although the data is quite old, the chemical shifts and coupling constants given in Table 1 are reliable enough to confirm the structure of the carbohydrate component of a pentaglycosylceramide of the globo-series (see Figure 4) and its lower homologues. Even with a low field instrument, the size of the coupling constant of each glycosidic proton gives its anomic configuration. In the example cited in Table 1, the coupling constants for the α- and β-N-acetyl-D-galactosaminosyl and α- and β-D-galactosyl residues are distinct. Apart from sugars with the manno-configuration, α-glycosidic protons have J_{1,2} coupling constants of 3–4 Hz while β-anomers show values of 7–9 Hz. As with other procedures, the amphiphatic nature of glycolipids means that special solvent systems are necessary for dissolution. Many reports use 2% D_{2}O in deuterated DMSO while others use pyridine-d_{5}.

The introduction of instruments with field strengths up to 800 MHz can give unambiguous results with as little as 100 µg of glycolipid. Future generations of instruments are unlikely to improve significantly on this lower limit. For a straightforward 1-D 1H spectrum, 400 MHz instruments allow the coupling constants to be obtained not only of the anomic protons but all of the protons attached to the ring carbon atoms to be assigned and determined. Thus, an unambiguous assignment of each sugar residue and its configuration is obtained.

The theory and practice of NMR spectroscopy has advanced greatly since the mid 1970s with the introduction of 2-D spectroscopy and related methods and there are many general reviews (see, for example, Goldman). Few are specifically applied to glycolipids although animal glycospingolipids have been and plant glycadiacylglycerols are included in a general review. The different types of 2-D NMR spectra can be classed under shift correlation spectroscopy (COSY) methods or spin-lattice relaxation methods. The latter are due to the time-dependent interaction between two spins.
producing a cross-reaction, or nuclear Overhauser effect spectroscopy (NOESY). There are further refinements of each technique and for more information relevant papers should be consulted.

As one example, the conformational analysis of the ganglioside GD1a has been determined by a NOESY method (see Figure 8 for 2-D spectra). The inter-residual hydrogen distances calculated from the NMR data were in good agreement with the lowest energy model previously suggested. The internal and branched sialic acid residue is stacked underneath the N-acetyl-D-galactosamine residue with a hydrogen bond between the carboxy group of the sialic acid and the amino group of the N-acetyl-D-galactosamine residue. Both sialic acid residues are orientated almost perpendicular to the plane of the neutral tetrasaccharide core. By contrast, the structural analyses of the oligosaccharide chains of glycolipids were determined by magnetic transfer methods. COSY and homonuclear Hartmann Hahn (HOHAHA) methods were able to extract subspectra of constituent monosaccharides and identify their sugar type.

NMR has been used to understand the arrangement of glycolipids in bilayer membranes. The sphingolipid metabolites behaved as single populations of lipid amphiphiles that were uniformly dispersed in the membrane and displayed rapid symmetric motion about their long molecular axis. The whole area of the application of NMR to lipid phase behavior and lipid diffusion has been reviewed.

5.2.2 $^{13}$C Nuclear Magnetic Resonance

Far more structural information can be obtained from a $^{13}$C-NMR spectrum than from $^1$H-NMR. Owing to the low natural abundance of the $^{13}$C isotope, the technique does suffer from the need for relatively large quantities of the native glycolipid. A specific example of the technique was the elucidation of the structure of the digalactosyldiacylglycerol present in oat grain. By using $^{13}$C-NMR, as well as $^1$H-NMR, the identity of the glycosyl moieties in the polar head group, the linkage position between the groups and the anomeric configuration of the moieties were all determined.

$^{13}$C-NMR has also been used to determine the positional distribution of fatty acids in glycochylcerolipids from different plant families. The acyl carbonyl shifts of fatty acids attached at C-1 are downfield from those of C-2. In addition, the shifts also depend on the distance to the nearest double bond. Hence, plant families with high proportions of all-cis-$\Delta$-7,10,13-hexadecatrienoic and all-cis-$\Delta$-6,9,12,15-octadecatetraenoic acids could be determined and the results were in agreement with the distribution as determined using a lipase.

Glycosylation is a common co- and post-translational modification of a protein which may have profound effects on protein structure and function. Many biologically interesting proteins are glycosylated at their asparagine, serine, and threonine residues. Glycosylation has now been recognized as being more ubiquitous and structurally varied than all other types of post-translational modifications combined. The glycosylation pattern of a glycoprotein is not random but is dependent on cell type, physiological conditions and, in some cases, disease states. Carbohydrate chains or glycans attached to the peptide backbone are classified according to the nature of the linkage to the peptide and their structure; both of these parameters allow the definition of common cores. In addition to the extreme structural diversity and complexity of glycan structures, one feature of protein glycosylation is the presence at a single site of any one of a number of glycan structures. This property gives rise to an extremely heterogeneous population of glycoproteins, termed glycoforms.

Indirect methods such as immunological approaches using antibodies or lectins provide some structural information concerning the nature of glycans. Prior to their structural study, glycans have to be released from the protein backbone by enzymatic or chemical methods. Different endoenzymes such as N-glycanase allow a complete deglycosylation of glycoproteins, providing a pool of oligosaccharides which may be further fractionated. Establishment of the site heterogeneity and assessment of the different glycoforms require isolation and analysis of the individual glycopeptides generated after hydrolysis with specific proteases. Fractionation of glycans or glycopeptides can be achieved by different high-performance liquid chromatography (HPLC) or electrophoretic procedures. Lectins, due to their extreme specificities with regard to monosaccharide or oligosaccharide motifs, represent powerful tools for sequential glycan fractionation.

Traditionally, a complete structural analysis of the glycan structures, including determination of the carbohydrate sequence and the sugar linkage, has been a tedious, multidisciplinary task. Characterization and determination of the relative amount of individual constituent monosaccharides is generally obtained by gas–liquid chromatography (GLC) after hydrolysis of the oligosaccharide chain. Information concerning the nature of linkages and branching points is furnished by the methylation procedure. Nevertheless, these chemical sequencing methods often necessitate milligrams of material. To progress from this situation, sensitive physicochemical or enzymatic methods have been developed. The nuclear magnetic resonance (NMR) study of oligosaccharides, even of the less sensitive of the physicochemical techniques, is extremely powerful because it allows determination in a mixture of glycans, the complete structure of individual glycans including nature of monosaccharides, sequence, type of linkages, anomericity and branching points. The recent advances in mass...
spectrometry (MS) techniques, mainly matrix-assisted laser desorption/ionization (MALDI) or electrospray ionization (ESI), have provided very sensitive means for the analysis of oligosaccharides and glycopeptides. The gain in sensitivity associated with a minimum number of sample manipulation steps allows work at the submicrogram level. The use of enzyme reagents is rapidly becoming popular in modern carbohydrate analysis because of their inherent selectivities for a sugar substrate and its linkage type. Exoglycosidases can be used in conjunction with other methods such as MALDI/MS or fluorophore-assisted carbohydrate electrophoresis (FACE) separation. Complete structural information is now feasible for low-microgram and submicrogram quantities of a glycoprotein; this quality of performance places the field of carbohydrate analysis closer to the sequencing methods available for other biomolecules, proteins or nucleic acids.

1 INTRODUCTION

In 1907, The American Society of Biological Chemists and the American Physiology Society defined the glycoproteins as “compounds of the protein molecule with a substance or substances containing carbohydrate other than nucleic acid”. In 1986, the International Union of Pure and Applied Chemistry–International Union of Biochemistry (IUPAC–IUB) Joint Commission on Biochemical Nomenclature \(^1\) described glycoconjugates as various types of compound consisting of carbohydrates covalently linked with other types of chemical constituent. This general definition of glycoconjugates includes glycoproteins, glycopeptides, glycolipids, peptidoglycans, and lipopolysaccharides.

This article refers only to glycoproteins and glycopeptides, which are compounds containing one or more oligosaccharides or glycans covalently linked to the polypeptide chain by a glycosyl linkage.

According to the type of glycosylation, the family of glycoproteins may be subdivided into glycoproteins, mucins, and proteoglycans. The glycans linked to the polypeptide chain of the proteoglycans are called glycosaminoglycans. The glycosaminoglycans are linear polymers of alternating residues of hexosamine and uronic acid or galactose. They are often sulfated at various positions.\(^2,3\) A survey of methodological challenges for glycosaminoglycan/proteoglycan analysis has been published recently.\(^4\) The glycoproteins are ubiquitous components. They result from an enzymatic addition of glycans to the proteins biosynthesized by viruses, many archaeabacteria, some eubacteria, plants, and animals. The glycosylation step of a protein represents one of the most important post-translational modifications of this protein.

Glycoproteins are widely distributed in biological fluids mainly in serum, intracellularly, and at cell surfaces. The mucins are highly glycosylated proteins found at the surface of all mucosa. Mucin-like components have been identified at cell surfaces, mainly in cancer cells. Significant advances in the understanding of the structure and the biosynthesis of glycoproteins have revealed that different glycans may be linked to an individual glycosylation site, leading to a mixture of glycovariants or glycoforms within a single polypeptide chain.\(^5\) In parallel with our increasing knowledge of the glycoprotein structures, important functional roles of glycans have been recognized, not only in the modulation of the conformation and the physicochemical properties of the protein, but also in the biological interactions of the glycoforms with free or membrane target molecules. Most of the recent advances in structure and function of the glycoproteins have been extensively reviewed.\(^6–11\)

Recombinant antibodies, hormones, and enzymes are now produced for clinical applications. A connection between the biological functions of these recombinant glycoproteins and the structure of their glycans has been established.\(^12\) Arising from the importance of the development of genetic engineering techniques for the production of recombinant glycoproteins, techniques are becoming necessary for rapid and reliable determination of the glycan structure as well as for the glycan distribution among the different glycosylation sites.

This article describes the general features of the glycan structures found in glycoproteins and mucins, and a combination of chromatographic techniques is proposed for their isolation and structural characterization.

2 GLYCAN STRUCTURES: AN OVERVIEW

Recent advances in the physical methods used to determine the primary structure of glycoprotein glycans now enable the analysis of very small amounts of material. This has rapidly increased the number of glycan structures, more than 1500 of which are now gathered in the CarbBank. The diversity of these glycans is mainly explained by the nature of the covalent carbohydrate–protein linkage, the composition in monosaccharides, the branching of the structures, and the origin of the glycoproteins.

2.1 Carbohydrate–Protein Linkage

For a long time the only two types of covalent linkages known were N-glycosylated (alkali stable) and O-glycosylated (alkali labile). In the N-linked glycans, the nitrogen of the side chain of an asparagine is linked to the $\beta$-anomeric carbon of an N-acetylglucosamine
and constitutes the 2-acetamido-N-(L-aspart-4-yl)-2-deoxy-β-D-glucopyranosylamine or \(N^4\)-(N-acetyl-β-D-gluco-aminyl)asparagine linkage. The asparagine residue belongs to the peculiar sequon AsnX (Ser or Thr, and rarely Cys) of a polypeptide chain \(\text{Asn} - L\)-asparagine; \(\text{Ser} = \text{serine}; \text{Thr} = \text{threonine}; \text{Cys} = \text{cysteine}\). Here X is any amino acid except proline (which completely blocks the glycosylation) and some amino acids such as tryptophan, glutamic acid, aspartic acid, or leucine (which create conformational constraints and partially inhibit the glycosylation). All Asn residues included in the triplet are not glycosylated, because the glycosylation depends on the accessibility of the sequon to the oligosaccharyltransferase, which transfers the complete immature oligosaccharide to the asparagine. In bacterial glycoproteins, the \(N\)-acetylgalactosamine linked to Asn is replaced by an \(N\)-acyetylglucosamine, a glucose, or a rhamnose residue (Table 1). In O-glycosidically linked glycans, the anomeric carbon of a monosaccharide is attached through an \(\alpha\) - or \(\beta\)-glycosidic linkage to the hydroxyl oxygen of serine, threonine, hydroxysyne, hydroxyproline or tyrosine (Table 1). The \(N\)-acetyl-\(\alpha\)-D-galactosaminyl-Ser or -Thr is the most common carbohydrate–protein linkage found in the mucins. Proposed peptide motifs containing Ser and Thr specifying \(O\)-glycosylation sites have been described and a database containing the sequences around \(O\)-glycosylation sites is on the Internet. Recently, a fundamentally different kind of protein glycosylation has been found in which the C2 atom of tryptophan is attached by a C–C linkage to the anomic carbon of an \(\alpha\)-mannose residue. This C-mannosylation of tryptophan has been shown by tandem electrospray MS analysis in human ribonuclease 2. In addition to \(N\)-, \(O\)-, and \(C\)-glycosyl linkages, in membrane glycoproteins, the anchor of the glycolipid glycosylphosphatidylinositol (GPI) is conjugated to the protein C-terminus through an amide bond.

### 2.2 Carbohydrate Composition

A landmark for the carbohydrate composition of a mature \(N\)-glycosylated protein is the presence of the monosaccharides D-mannose (Man), \(N\)-acetyl-D-glucosamine (GlcNAc), D-galactose (Gal), L-fucose (Fuc), \(N\)-acyetyl-D-galactosamine (GlcNAc), D-xylose (Xyl), L-furanoarabinose (f-Ara), and sialic acids which are various derivatives of neuraminic acid, mainly \(N\)-acyetyl-neuraminic acid (Neu5Ac) and \(N\)-glycolyneuraminic acid (Neu5Gc). During biosynthesis, immature glycans contain one to three residues of Glc involved in the trisaccharide structure Glc(\(\alpha\)-1–2)Glc(\(\alpha\)-1–3)Glc(\(\alpha\)-1–3) linked to the oligomannosidic type glycan Man\(_n\)GlcNAc\(_n\). The presence of glucuronic acid (GlcA) is not common in \(N\)-linked glycans. In O-linked glycans, the main monosaccharides are GalNAc, Gal, GlcNAc, Fuc, and sialic acids. Even if mannose has been found in some O-linked glycans, it is considered to be unusual here. Other peculiar monosaccharides, such as the deamidated neuraminic acid 2-keto-3-deoxyxynononic acid (Kdn) and various O-sulfated, O-phosphorylated, O-methylated and methyl O-phosphorylated monosaccharides, have been identified either in O- or N-linked glycans. The monosaccharides found in glycoproteins have the pyranose configuration and sometimes the unusual furanose configuration.

### 2.3 \(N\)-linked Glycoproteins

**2.3.1 General Structure of \(N\)-Glycans**

The structure of \(N\)-linked glycans is very heterogeneous; however, all glycans possess a pentasaccharide core constituted of two \(N\)-acetylgalactosamine and three mannose residues (Figure 1). This backbone may be substituted either by one \(N\)-acyetylglucosamine (known as the intersecting GlcNAc residue), one xylose, or one to two fucose residues. The complexity of the glycan structures results from the addition to Man(\(\alpha\)-1–3) and Man(\(\alpha\)-1–6) of one to five \(N\)-acyetylglucosamine residues. In fact, these

Figure 1 Modifications of the pentasaccharide core of \(N\)-glycosylated proteins.

GlcNAc initiate a branching and generate di-, tri-, tri\'-, tetra-, and pentaantennary glycans\(^{19}\) (Figure 1). In mature glycans, extension of the branching is realized by addition of various peripheral structures including Gal, GlcNAc, GalNAc, Fuc, and sialic acids in order to complement the antennae (Figure 2). The glycan structures obtained are called \(N\)-acytlylglactosamine or complex type, and when the extension consists of several \(N\)-acytlylglactosamine units (Gal(\beta 1\rightarrow 4)GlcNAc) associated by a (\(\beta 1\rightarrow 3\)) linkage, the structures are called polyacytlylglactosamine type.

Analysis of the three-dimensional structure of glycans has revealed that the pentasaccharide core is rigid whereas the antennae are mobile. The glycans have interactions with the polypeptide chain and occupy an important volume at the surface of the glycoprotein.\(^{20,21}\)

2.3.2 Biosynthesis of \(N\)-Glycans

Biosynthesis of the \(N\)-linked glycans and the control of glycosylation induced by the conformation of the polypeptide chain are now well established. This biosynthesis involves, in the first step, the transfer of the oligosaccharide (Glc\(_{3}\)Man\(_{9}\)GlcNAc\(_{2}\)) from a dolichylopoligosaccharide precursor to the nascent polypeptide chain. Mature glycans are obtained following the activity of trimming glycosidases (\(\alpha\)-glucosidases and \(\alpha\)-mannosidases) and specific glycosyltransferases found in the endoplasmic reticulum and the Golgi apparatus.\(^{22,23}\)

During the biosynthesis, it may be noticed that the glycan structure is affected by the compartments traversed within a cell and also by the speed with which the glycoprotein passes through these different compartments. Examples of oligomannose or high mannose, hybrid and biantennary \(N\)-acytlylglactosamine glycan structures obtained during the biosynthesis pathway and found in the structure of native glycoproteins are given in Figure 3.

2.3.3 Variability of Glycosylation

A systematic and comparative study on glycan primary structures of transferrin from biological fluids of different species has revealed that the glycosylation pattern of the individual transferrin molecule depends
on the glycosyltransferase activities of the cell and of the species. The cell specificity, tissue specificity and species specificity of glycosylation are now well established and have important implications. For instance, the glycosylation pattern of recombinant glycoproteins is highly dependent on the glycosyltransferase activities of the cell. As only few bacteria possess glycosylation capacities, yeast, insect cells, plants, and animal cell lines have often been used as systems for expressing recombinant glycoproteins. Examples of typical glycan structures biosynthesized by various cells are given in Figure 4. The high variability of the glycan structures found in a given recombinant glycoprotein expressed in various cells may provide an explanation for some divergences in the physicochemical, biochemical, immunological and functional properties of the resultant recombinant glycoforms.

A specific set of glycans is attached to a unique glycosylation site. For instance, in human serum transferrin, the two glycosylation sites are occupied by either bi-, tri-, tri', or tetraantennary glycans leading to different glycoforms. These glycoforms have been separated using lectin-affinity chromatography, anion-exchange chromatography, isoelectric focusing or ESI/MS. In normal physiological conditions, the percentages of these glycoforms are reproducible. However, high variations in these percentages appear during development, differentiation, and under modifications of the normal physiological state. The nature of the different factors involved in the alterations of glycosylation is not yet known; however, the modulatory effects of hormones or cytokines during pregnancy or inflammation have been described.

2.3.4 Biological Roles of N-linked Glycans

The N-glycans are recognized as components having many functional roles and the new science of glycobiology has been developed. It is difficult to predict the function of a given glycan, because the same glycan may be associated with various functions in different glycoproteins. Of the numerous functions attributed to N-glycans, some are important to the glycoprotein itself, mainly for its folding, solubility, protease sensitivity, antigenicity, intracellular location, and biological half-life. In general, the peripheral sequence of a glycan represents the most important functional part of this glycan. This peripheral part may be involved in specific carbohydrate–carbohydrate interactions or carbohydrate–protein interactions which generate most of the biological processes in which the glycoproteins are involved. For instance, the mechanism of recognition is responsible for the following: binding of asialoglycoproteins to the hepatic cell receptor which specifically recognizes terminal Gal and GalNAc residues and which is involved in the clearance of the asialoglycoproteins; the specific binding of pathogens to the cells of the immune system; or the specific targeting of enzymes possessing a glycan with Man-6P to the lysosomes. An aberrant glycosylation of glycoproteins may alter

Figure 3 Representative structures of the three types of N-glycosidically linked glycans.
the intra- and intermolecular functions of the glycans. The science of glycopathology is now developing and some correlations between the modifications of glycosylation patterns and pathology have been established. A better understanding of the fine variations in glycan structures and in the relative proportions of the glycoforms, at different stages of a disease, appear relevant to diagnosis.

Progress in genetic engineering has allowed the biosynthesis of a multitude of recombinant glycoproteins used for pharmaceutical applications. The most important problem encountered concerns the biosynthesis of a panel of glycoforms, which should be similar to the panel biosynthesized in vivo. Variations in glycosylation of recombinant glycoproteins may induce alteration in intercellular targeting and clearance and may therefore inhibit their therapeutical activity.

2.4 O-linked Glycoproteins

2.4.1 General Structure of O-linked Glycans

In glycoproteins such as yeast glycoproteins, secretory immunoglobulin A, and glycophorin, a limited number of O-linked glycans is found associated with N-linked glycans, whereas in mucins, several hundred to several thousand of these glycans are clustered in highly glycosylated domains. The structure of the O-glycans is also very heterogeneous. The diversity depends on the nature of the core and the chain length, which may comprise 1–20. All these glycans are based on the same structural model, made of three distinct regions: the core, the backbone, and the periphery. To date, eight cores including the GalNAc attached to the hydroxy amino acid and Gal, GlcNAc and GalNAc residues have been characterized (Figure 5).

- Gal(β1–4)GlcNAcβ (Type II)
- Gal(β1–3)GlcNAcβ (Type III)

Figure 5: Cores and backbones found in O-glycosidically linked glycans.

Linked to the cores are six types of backbone, the most common being the iso-N-acetyllactosamine unit (Gal(β1–3)GlcNAc; type I) and the N-acetyllactosamine unit (Gal(β1–4)GlcNAc; type II). The periphery is made of different monosaccharides (Gal, GalNAc, Fuc, NeuAc) which may be assembled in repeated units. Examples of typical and peculiar O-linked glycans found in various glycoproteins are given in Figure 6.\(^{(45–48)}\)

2.4.2 Biosynthesis of O-linked Glycans

In contrast to the biosynthesis of N-linked glycans, the biosynthesis of O-glycans is not performed by a transfer from a dolichyl–oligosaccharide precursor to the protein, but by a sequential addition of a monosaccharide from a nucleotide monosaccharide. In mucins, the UDP-GalNAc polypeptide α-N-acetylgalactosaminyltransferase is the enzyme which conjugates the first GalNAc residue to the completely folded apoprotein. Several types of this enzyme have been characterized. The eight cores result from the addition of Gal, GlcNAc, and GalNAc residues by α- or β-glycosyltransferases, whereas the backbones are synthesized by the action of two types of β-galactosyltransferase and two types of β-N-acetyl-glucosaminyltransferase. Addition of the monosaccharides found in the peripheral part is performed essentially by α-glycosyltransferases. The numerous glycosyltransferases involved in the biosynthesis of O-glycans are specific and almost localized in the Golgi apparatus.\(^{(49,50)}\)

2.4.3 Biological Roles of O-linked Glycans

Like the N-linked glycans, the O-linked glycans are involved in intra- and intermolecular interactions and these interactions are increased by the fact that the O-glycans are often found in glycoproteins and mucins as clusters.\(^{(14,51)}\) The presence of a cluster of sialylated and sometimes sulfated O-glycans confers to the polypeptide chain an extended conformation, a protection against the protease activity and heat denaturation. O-Glycans present in membrane glycoproteins have been recognized as receptors for viruses, bacteria, and pathogens. Antigenic determinants responsible for A, B, H, Le\(^{a}\), Le\(^{b}\), and

glycerophosphatidylinositol is linked to a glucosamine residue from the linear tetrasaccharide Man(α1–2) Man(α1–6)Man(α1–4)GlcNH₂(α1–6). The diversity of GPI anchor structure depends on substitution of the core. Although little is known about the enzymes involved in the biosynthesis of a GPI anchor, the different steps in the biosynthesis of the trypanosomal GPI anchors have been well established.⁵⁶ The methods used to isolate and identify the complete structure of a GPI anchor are not described here.

3 GLYCOProTEIN ISOLATION AND CHARACTERIZATION

Many methods are available for glycoprotein isolation. The conventional chromatographic methods of glycoprotein fractionation are based on molecular mass (gel permeation chromatography), surface charge interactions (ion-exchange chromatography) and surface hydrophobic interactions (hydrophobic chromatography). More selective glycoprotein isolation methods are based on interactions of the protein moiety with specific monoclonal or polyclonal antibodies (immunoaffinity chromatography) and the interactions of glycan moiety with lectins (lectin-affinity chromatography).

The use of these different column chromatography techniques (alone or in combination, performed at low or high pressure) can isolate pure glycoproteins (in a single step or in several steps). The purified glycoproteins are often composed of a mixture of glycoforms which differ by their degree of sialylation and therefore by their isoelectric point. To isolate the glycoforms, additional methods are often necessary based on electrophoresis, such as capillary electrophoresis, sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE), and isoelectric focusing.

This review concentrates first on immunoaffinity chromatography, which can be used (if specific antibodies are available) before other methods to extract a pure glycoprotein from a sample. Secondly, anion-exchange chromatography and lectin-affinity chromatographic methods, which are able to separate the glycoforms, are considered.

3.1 Mucin Isolation

3.1.1 Isolation of Mucins Requires Specific Methods

Due to their high molecular weight and their extreme diversity both in peptidic backbone and carbohydrate content, the isolation of mucins requires specific isolation methods.⁵⁷–⁵⁹ Mucin can be collected from mucosal cells by scraping of the tissue surface using guanidine hydrochloride/phosphate-buffered saline...
(PBS) at pH 7.0. Generally mucins are contaminated with proteoglycans, nucleic acids, and other glycoproteins. The first steps of purification consist of molecular-weight-based fractionation using repeated ultracentrifugation on a cesium chloride gradient in the presence of concentrated guanidine solutions. The samples are centrifuged at 100–150,000 g for 24–48 h in order to generate a density gradient from 1.3 to 1.6 g mL⁻¹. Under these conditions, proteoglycans, nucleic acids, and mucins are well separated.

Further purifications steps of individual mucins can be achieved according to molecular size using gel filtration on Sepharose™ CL2B or Sephacryl S1000. As a result of their charge diversity in relation to their sialic acid and/or sulfate content, individual mucin glycoforms can be separated by anion exchange chromatography on an anion exchanger such as diethylaminoethyl (DEAE). All of these chromatographic procedures should be carried out in the presence of strong denaturing agents such as guanidine hydrochloride buffer, or by introduction of reducing agents such as dithiothreitol (1% w/v).

If subunits are required, reduction and alkylation of mucin samples are necessary. Finally, strategies based on immunoaffinity procedures, using specific antibodies directed against the tandem repeat of the protein backbone such as the Pro-Asp-Thr-Arg-Ala-Pro-Gly-Ser (PDTRAPGS) region, have been recently developed and may be used in the isolation of abnormal mucins expressed in pathological states such as cancer.

3.2 Immunoaffinity Chromatography

A one-step purification of glycoprotein may be performed using specific protein monoclonal or polyclonal antibodies immobilized on different supports. Numerous methods have been used for preparing immobilized antibodies. Protein immobilization to CNBr-activated gel (agarose, Sepharose™, Ultrogel®) is the most popular choice. A major drawback found in protein affinity gel preparation by activation of Sepharose™ with CNBr concerns the introduction of charged groups into the matrix. This is avoided when the proteins are immobilized on polyacrylic-hydrazido-Sepharose™ support. Immobilized proteins can also be prepared with activated agarose-containing N-succinimide esters that react with amino groups of the proteins.

In addition to these general techniques used for all kinds of proteins and many lectins, oriented immobilization methods have been described for antibodies. The different techniques of oriented immobilization of antibodies have been reviewed, such as the use of immobilized protein A or G, the use of immobilized antibodies against the Fc constant region of the antibodies to be immobilized, and the use of immobilized antibodies through the carbohydrate moiety after acid periodic oxidation.

The selection methods for the most appropriate monoclonal antibody to be immobilized and precise methods for binding, washing and the elution steps have been reviewed. In general, once the glycoprotein has been captured by the specific immobilized antibodies, elution of the glycoprotein is performed in acidic conditions and, to preserve the biological activity of the purified antibodies, eluted antibodies must be immediately neutralized. Immunoaffinity chromatography is also used for detection of analytes as they elute from other types of chromatographic columns. Advances in analytical applications of immunoaffinity chromatography have been recently reviewed.

3.3 Isolation of Glycoforms by Anion-exchange Chromatography

The glycoforms often differ by their charge and can be separated preparatively by using anion-exchange chromatography after careful optimization of the analytical conditions. For instance, to separate the 14 glycoforms of recombinant human erythropoietin, different methods of fractionation were used with the best results being obtained by DEAE-Sephacel chromatography. Anion-exchange HPLC has been used to fractionate mucins and to identify glycoforms. A very rapid separation of monosialylated and disialylated serum transferrin glycoforms was obtained by ion-exchange chromatography on a Mono Q HR 10/10 column using fast protein liquid chromatography (FPLC).

3.4 Isolation of Glycoforms by Lectin Affinity Chromatography

3.4.1 Problems of Lectin Specificity

Lectins are sugar-binding proteins or glycoproteins of nonimmune origin that can agglutinate cells and/or precipitate glycoconjugates. They possess at least two sugar-binding sites, the presence of which explains their ability to precipitate polysaccharides, glycoproteins, or glycolipids, and why they agglutinate cells.

Lectins have been now isolated from viruses, bacteria, plants, and from a variety of animal tissues and species. However, only plant lectins are now commonly used in research and in clinical laboratories for the detection and fractionation of soluble and membrane glycoproteins, as well as glycopeptides or glycans derived from these glycoproteins.

Lectins are often still classified according to the monosaccharide that inhibits the interaction between a lectin and a cell, or which allows the specific elution of a
bound glycoconjugate from an immobilized lectin column (Table 2).

Analysis of sequence data of plant lectins by protein sequencing and cDNA cloning, together with X-ray crystallography data and molecular modeling, result in classification by their three-dimensional structures, not taking into account their monosaccharide-binding specificity. In this way seven groups of plant lectins can be distinguished:

- The legume lectins with a 12-stranded β-sandwich structure.
- The monocot-binding lectins with a 12-stranded β-barrel structure.
- The Jacalin-like lectins with a β-prism fold.
- The Amaranth-like lectins.
- The chitin-binding lectins made of hevein-like domains.
- The type II ribosome-inactivating proteins (RIPs) which contain an enzymatically active A chain and a B chain with lectin activity.
- The cucurbitaceae phloem lectins, which are a small family of chitin-binding lectins, found in the phloem exudate of cucurbitaceae species.

The structural basis of selective monosaccharide recognition by plant lectins has been investigated by X-ray crystallography and is now well documented.\(^\text{77,78}\) It explains in terms of hydrogen bonds the low affinity (dissociation constant, \(K_d\), in the 0.1–10 mM range) found in the interaction between a monosaccharide and a given lectin. However, it is well known that, in most cases, complex oligosaccharides are several-thousand-fold more potent inhibitors of lectins than monosaccharides.\(^\text{79,80}\)

These high binding selectivities towards complex oligosaccharides, first determined by biochemists, are now also explained by X-ray crystallography studies in terms of extended binding sites on a lectin. In addition to some amino acids forming the monosaccharide-binding site, other amino acid residues are involved in additional direct and water-mediated contacts between oligosaccharides and the lectin surface.\(^\text{78,81,82}\)

It is very important to know the complex specificity before using a lectin – as a probe in the exploration of cell surface glycoconjugates or as a tool to fractionate various glycoconjugates by affinity chromatography.

**3.4.2 Determination of the Complex Specificity of Lectins**

The specificity of lectins towards monosaccharides or oligosaccharides of glycoproteins or glycolipids can be determined by inhibition experiments in which monosaccharides or oligosaccharides of known structures are tested for their ability to inhibit either hemagglutination\(^\text{80}\) or precipitation of polysaccharides.\(^\text{83}\) However, a major drawback of these methods is that they require large quantities of oligosaccharides that are often available only in limited amounts.

A second approach to determine the complex specificity of a lectin is to study the affinity of the immobilized lectin towards complex oligosaccharides.\(^\text{84,85}\) In this approach, lectins are first immobilized on insoluble matrices. Small columns containing 2–10 mL of the immobilized lectins are then prepared and equilibrated in an appropriate buffer; the behavior of radiolabeled oligosaccharide or glycopeptides of known structure applied to these columns is then examined.

This second approach is of particular interest because it calls for only small amounts of oligosaccharides and, once the precise specificity of an immobilized lectin is established, it becomes possible to predict the primary structure of glycopeptides or oligosaccharides displaying similar elution profiles.

Specificities of lectins can be also studied using more sophisticated methods including isothermal titration microcalorimetry (ITC)\(^\text{86}\) or real-time interaction by surface plasmon resonance with biosensors.\(^\text{87}\)

### 3.4.3 Specificity of Lectins Towards Complex Oligosaccharides

From all these studies, important conclusions can be drawn about the carbohydrate-binding specificity of plant lectins. Lectins can interact with internal oligosaccharidic sequences of a glycan. Very few lectins recognize terminal nonreducing monosaccharides on a glycan and most of them recognize internal sequences of oligosaccharides. Lectins identical in terms of monosaccharide specificity can display different complex specificity. Both concanavalin A (Con A) and *Lens culinaris* agglutinin (LCA) display the same monosaccharide specificity for α-Man or α-Glc. However, as shown in Table 3, they display a higher affinity for different N-glycosylpeptides and related oligosaccharides. In particular, the presence of a fucose residue at the C-6 position of the GlcNAc residue involved in the N-glycosylamine linkage in a biantennary N-acetyllactosamine-type glycopptide enhances the affinity of LCA for this glycan and is an important determinant for the glycan-binding specificity of the lectin.\(^{80,88}\)

Moreover, a given lectin can recognize very different oligosaccharide sequences. For example, Con A has a strong affinity for oligomannoside type as well as for some hybrid-type glycans and a weaker one for biantennary N-acetyllactosamine-type glycans (Table 3).

These complex glycan specificities of plant lectins result from the existence of extended carbohydrate-binding sites on the lectins.

It is also worth noting that different lectins can recognize different saccharide sequences on the same glycan. As these sequences are common to numerous glycoproteins, results obtained with immobilized lectins during a fractionation of glycoproteins or by Western blot analysis of glycoproteins with lectins must be interpreted with caution.

The spatial conformation of glycans may affect their interaction with many lectins. Some lectins, such as LCA or wheat germ agglutinin (WGA) show a stronger affinity for N-glycosylpeptides containing the recognized oligosaccharide sequences than for the glycans released from these glycopeptides either by chemical or enzymatical cleavages and still containing the oligosaccharide determinants. This can be explained by the fact that the attachment of a glycans to asparagine imposes on the trisaccharidic core sequence Man(β1→4)GlcNAc(β1→4)GlcNAc(β1→N)Asn a rigid structure that favors the specific recognition of the oligosaccharidic sequences on the glycan by a given lectin.\(^{89}\) Some lectins such as *Ricinus communis* agglutinin I (RCA I) present a higher affinity for oligosaccharide sequences substituted by sialic acid residues bound in the α-2,6 position of galactose rather than in the α-2,3 position. This can be related to the higher mobility of sialic acid residues around the α-2,6 linkage.\(^{80,90}\)

However, for *Phaseolus vulgaris* phytohemagglutinins (PHAs) with erythro-agglutinating or leuco-agglutinating activities (E4-PHA and L4-PHA, respectively), this higher mobility of the sialic acid residues around the α-2,6 linkage can mask the internal oligosaccharidic determinants. This can explain why sialylated glycans in the α-2,6 position of galactose are not recognized by these lectins, whereas sialylated glycans in the α-2,3 position of galactose interact with them.\(^{91}\)

The concept of a larger space mobility of oligosaccharide sequences around an α-1,6-glycosidic linkage compared to the higher rigidity imposed by the α-1,3 linkage can explain the higher affinity of some lectins such as LCA or L4-PHA for tri-antennary N-acetyllactosamine-type glycans (Table 3) in which one of the α-Man residues is substituted by the third antennae at the C-2 and C-6 positions, rather than for triantennary glycans containing another α-Man substituted at C-2 and C-4 positions.\(^{88,92}\)

Due to their extended carbohydrate-binding sites, most lectins will display very precise specificity towards well-defined oligosaccharide sequences belonging to either N- or O-glycosylproteins. Therefore, classifications of lectins according to monosaccharide specificity must be superseded by classifications taking into account the concept of dominant oligosaccharides as recognized by lectins at either internal or peripheral positions on a glycan. However, a few lectins will present a specificity towards terminal nonreducing dominant monosaccharides.\(^{93–105}\)

Table 3 lists the specificity of some commonly used lectins towards oligosaccharide sequences belonging to N-glycosylproteins.

### 3.4.4 Use of Immobilized Lectins for Fractionation of Glycoproteins

#### 3.4.4.1 Immobilization of Lectins

Numerous methods have been proposed for preparing immobilized lectins and many of them are now available from different suppliers (Pharmacia Biotech, E. Y. Laboratories, Sigma Chemical Co, Vector Laboratories). Lectins immobilized to CNBr-activated agarose are the most popular and can be easily prepared at a density of 2–10 mg of lectin per milliliter of settled gel (agarose, Sepharose\(^\text{™}\) or Ultrogel\(^\text{™}\)) activated with CNBr according to the procedures of March et al.\(^{60}\) or Kohn and Wilchek.\(^{61}\)

Immobilization of lectins on polyacryl-hydradizo-Sepharose\(^\text{™}\) support according to Wilchek and Miron\(^{62}\) does not introduce charged groups into the matrix, a major drawback found in lectin affinity gels prepared by activation of Sepharose\(^\text{™}\) with CNBr.

Immobilized lectins can be prepared with activated agarose containing N-hydroxysuccinimide esters which react with amino groups of lectins. These activated gels are available from BioRad as Affi-Gel® 10 or Affi-Gel® 15.

All these gels can be used in low-pressure chromatography with flow rates of 5–20 mL h⁻¹. However, lectins can be also immobilized on activated supports compatible with HPLC (flow rate of 1 mL min⁻¹). This technique combines the high speed and resolution
3.4.4.2 Fractionation of Glycoproteins on Immobilized Lectins

Affinity chromatography on immobilized lectins is now widely used to fractionate either soluble or membrane glycoproteins, and many examples have been reviewed elsewhere.\(^\text{97,108–113}\) Highlighted here are some particular points which can be useful during such fractionations.

Variations in the amount, as well as in the quality of the lectin immobilized on a gel, represent important factors influencing the binding of glycoproteins. For example, affinity differences are often observed between different commercially available immobilized Con A. This requires the calibration of the lectin column with well-known glycoproteins before using a new batch of immobilized lectin.

Three fractions are generally obtained, reflecting relative affinities of the glycoproteins for the immobilized lectins.

The nonreactive glycoproteins are eluted at the void volume of the column in the equilibration buffer. This fraction, when the exact capacity of the immobilized lectin is not known, must be submitted to a new cycle of absorption and elution on the same column, to be certain that the immobilized lectin was not saturated during the first run. In order to limit nonspecific interactions between glycoproteins and immobilized lectins, equilibration buffers must possess a moderate ionic strength (0.1–1.0 M in NaCl, for example).

The weakly reactive glycoproteins give fraction(s) that are recovered by elution with the equilibration buffer as retarded fraction(s). In this case, the separation of weakly interacting glycoproteins can be obtained by using a long and thin lectin column, this is more efficient than a wider and shorter column containing the same amount of immobilized lectin. The spatial conformations of the native glycoproteins or nonspecific hydrophobic interactions may modulate the accessibility of some glycans to the lectin and can explain the presence of some artefactual weakly reactive fractions. These fractions are absent when the glycoproteins are reduced and alkylated before fractionation on the immobilized lectin.\(^\text{114}\)

Strongly reactive glycoproteins are specifically eluted after extensive washing with the equilibration buffer containing the competitive monosaccharide (0.1–0.5 M). After extensive washing with the equilibration buffer, the immobilized lectin can be used again with the same efficiency. Stronger lectin–glycoprotein interactions may result either in very high affinity of the lectin for some oligosaccharidic determinants of a glycoprotein or in the multivalent interactions between the immobilized lectin and a very high density of a saccharidic determinant of the glycoprotein recognized by the lectin (avidity effect). In the particular case of immobilized Con A, the recovery of high-affinity glycoproteins can be improved by raising the temperature of the 0.5 M methyl-\(\alpha\)-D-glucoside or \(\alpha\)-D-mannoside solution to 37°C or even 60°C. However, very often these strong interactions could be reversed only with nonspecific desorption processes which may cause irreversible denaturation of the immobilized lectin. Such nonspecific elutions can be performed by pH changes with either 20 mM acetic acid or diaminopropane solutions or with 0.02–0.1 M borate buffers (pH 8.0), without denaturation of the lectin.

High-yield recovery can also be obtained by heating the immobilized lectin–glycoprotein complex for 3 min at 100°C in buffer containing 5% (w/v) sodium dodecyl sulfate (SDS) and 8 M urea, but with irreversible inactivation of the lectin.

The sequential use of immobilized lectins, with different and well-defined specificities towards saccharidic determinants, can be applied to fractionate complex mixtures of glycoproteins into classes depending on their affinities for the different lectins. Immobilized Con A, LCA, and WGA are the most commonly used.

When lectin affinity chromatography is used to fractionate membrane glycoproteins, the most important problem is the stability of the immobilized lectin in the detergent solution utilized for membrane protein extraction. This detergent must be present during all further purification steps of the solubilized membrane glycoproteins. However, this detergent may dissociate the lectin into subunits or change their active conformation. As shown by Lotan et al.,\(^\text{115}\) nonionic detergents such as Triton\(^\text{®}\) X-100 at 0.1% concentration in the running buffer remain the most compatible with lectin affinity chromatography of membrane glycoproteins.

3.4.4.3 Limitations of Lectin Affinity Chromatography in Purification of Glycoproteins

Affinity chromatography on immobilized lectins rarely permits the purification of a given soluble or membrane glycoprotein from complex mixtures in a single step. This method usually fractionates glycoproteins into different classes containing similar glycans. As different lectins will be able to recognize different saccharidic sequences, but belonging to the same glycan, sequential affinity chromatography on different immobilized lectins will not improve the fractionation significantly.

However, a few membrane or soluble glycoproteins have been isolated in one step from complex mixtures by lectin affinity chromatography. For example, immobilized WGA allows the purification of either glycofiltrin, the major human erythrocyte membrane glycoprotein,\(^\text{116}\) or the insulin receptor\(^\text{117}\) in a single step. Laminin, a major...
component of basement membrane, can be purified in one step on an immobilized *Griffonia simplicifolia* agglutinin I (GSA I-B4) lectin column.\(^{118}\)

Human IgA1 and IgD can be isolated in one step from human sera on an immobilized *Artocarpus integrifolia* lectin (Jacalin) column which strongly interacts with the O-glycosidically linked Gal(\(\beta 1\)–3)GalNAc determinants present in the hinge region of these glycoproteins.\(^{119–122}\)

\(\alpha\)-2 Macroglobulin from human sera is the only glycoprotein with oligomannosidic glycans recognized and eluted with a 0.1 M methyl-\(\alpha\)-D-mannoside solution from an immobilized *Galanthus nivalis* mannose-specific lectin, isolated from the snowdrop bulb.\(^ {123}\) However, lectin affinity chromatography usually fractionates glycoproteins into different classes containing similar carbohydrate determinants. Nevertheless, when a given glycoprotein can be purified in a first step from other contaminating glycoproteins, either by conventional biochemical procedures or by immunoaffinity chromatography, lectin affinity chromatography represents a very powerful tool with which to unravel the glycan microheterogeneity inside this glycoprotein.\(^ {124}\)

### 3.5 Characterization of Glycoprotein Glycosylation

#### 3.5.1 Glycan Detection Kits

Protein glycosylation can be easily and sensitively detected using different detection systems based on immunological labeling of glycoproteins on blots.\(^ {125–128}\) The procedures are based on oxidation of the adjacent hydroxyl groups of the monosaccharide constituents to aldehyde by mild periodate treatment and subsequent derivatization of the resultant aldehyde groups with either biotin or digoxigenin (DIG) via a hydrazide group. Biotin or DIG can be subsequently detected using either streptavidin or antidigoxigenin – alkaline phosphatase conjugate. An adaptation of the method consists in using biotin or DIG-labeled lectins, specific to the different constituent monosaccharides.

These methods are commonly used as a first step to assess both the occurrence and nature of glycans.

#### 3.5.2 Detection of Glycoproteins with Lectins after Separation by Polyacrylamide Gel Electrophoresis

The high resolving power of polyacrylamide slab gel electrophoresis either under native or denaturing conditions\(^ {129}\) or two-dimensional gel electrophoresis combining isoelectric focusing and SDS–polyacrylamide gel electrophoresis\(^ {130}\) allows excellent separations of protein and glycoprotein mixtures. These glycoproteins can be detected with lectins of well-defined specificity either by direct incubation of the gels with lectins or by incubation of the electrophoretically separated glycoproteins transferred onto various immobilizing matrices with lectins.

##### 3.5.2.1 Direct Application of Lectins to Polyacrylamide Gels

**Use of Radioiodinated Lectins.**\(^ {131}\) After electrophoresis, the slab gel slices are fixed and washed in a destaining solution containing 7.5% methanol and 7.5% acetic acid in water. After equilibration in Tris-buffered saline (TBS) (0.05 M Tris·HCl, pH 7.5; 0.15 M NaCl; 0.1% NaN\(_3\)), gel slices are put in a flat, humidified plastic box, overlaid with a radioiodinated lectin diluted in the equilibration buffer to 0.1–2.0 \( \times 10^7\) cpm mL\(^{-1}\) and incubated for 1–20 h.

After incubation, unbound lectin is washed out in several changes of equilibration buffer. Gel slices are then dried out and the lectin-reactive glycoproteins visualized by autoradiography.

In the overlay method, there is only binding of the radioiodinated lectin to glycoproteins on the overlaid face of the gel. Total immersion of the gel slices in the lectin solution will label both gel faces, but more lectin solution will be necessary.

For a given lectin, parallel gel slices must be incubated and washed in the presence or absence of 0.1 M competitive monosaccharide to detect any nonspecific binding.

On a gel slice, different glycoproteins can be revealed by a lectin because they possess the same oligosaccharide determinants recognized by the lectin. A single glycoprotein on a gel can be revealed by several lectins because of the possible glycan microheterogeneity of this glycoprotein, but also because different saccharide sequences belonging to a single glycan can be recognized by different lectins.

**Use of Peroxidase-labeled Lectins.** After electrophoresis, separated glycoproteins can be also reacted with peroxidase-coupled lectins and detected by color development of the enzyme reaction.\(^ {132}\) Lectins can be easily coupled to horseradish peroxidase and many peroxidase-coupled lectins are commercially available. However, some lectins, such as Con A, can be used without any coupling procedure with peroxidase because of their multivalency and of their great affinity for the N-linked glycans of horseradish peroxidase. In the first step, the lectin will bind to the separated glycoproteins on the gel and, in the second step, the glycoprotein-bound lectin will bind to horseradish peroxidase, which will be visualized by the chromogenic reaction with 3,3′-diaminobenzidine as the substrate.
3.5.2.2 Detection of Glycoproteins after Transfer Onto Immobilizing Matrices

The transfer of electrophoretically separated proteins and glycoproteins onto immobilizing matrices was first described in 1979 by Renart et al.\textsuperscript{133} and Towbin et al.\textsuperscript{134} Since then, protein blotting has become the method of choice for detecting and characterizing proteins in complex mixtures.\textsuperscript{135,136}

After electrophoresis, the separated proteins and glycoproteins are transferred onto different immobilizing matrices under conditions that maintain the electrophoretic pattern. Electrot transfer is generally preferred to capillary transfer because of the increased speed and the improved resolution of the bands. Many immobilizing matrices have been described but the most popular are the cellulose nitrate (CN) and the microporous polyvinylidene difluoride (PVDF) membranes on which transferred proteins are strongly bound by interfacial (hydrophobic) interactions.

Transfer conditions must be defined with care. The composition of the transfer buffers, with or without methanol which promotes hydrophobic binding by stripping SDS from proteins and with or without SDS which increases the elution of high-molecular-weight proteins from the gel as well as the running conditions, depends on the proteins to be transferred.

After the transfer of proteins to immobilizing matrices, all the unoccupied potential binding sites of the matrices must be blocked to avoid unspecific binding of the detecting molecules. Electrotransferred glycoproteins can be visualized by incubation of the matrices with radioiodinated lectins, with biotin-conjugated lectins revealed with avidin-peroxidase, with peroxidase-coupled lectins or with DIG-labeled lectins revealed with anti-DIG antibodies conjugated either to alkaline phosphatase, to horseradish peroxidase or labeled with fluorescence markers.

In particular, the detection of glycoproteins on blots with DIG-labeled lectins represents a very sensitive method based on the use of the plant steroid DIG as a hapten which will be detected by antibodies (anti-DIG) with high affinity towards this hapten. DIG-labeled lectins as well as DIG antibody (Fab fragments) conjugated with alkaline phosphatase are available from Boehringer Mannheim (Mannheim, Germany).

Together with blots with electrotransferred glycoproteins, dot blots, prepared by spotting on nitrocellulose membrane glycopeptide-containing fractions obtained by different chromatographic methods, can be revealed by the DIG–lectin/anti-DIG–alkaline phosphatase system.

It is also noteworthy that, as electrotransferred glycoproteins are strongly bound on nitrocellulose or PVDF membranes, treatment of the immobilized glycoproteins with various endo- or exoglycosidases of known specificities, in combination with DIG–lectins of well-defined specificities, can provide structural information on the glycan moieties using minute amount of glycoproteins. However, reference glycoproteins with well-characterized glycans must then be included in the analyzed membrane in order to verify the efficiency of either the enzymatic treatment(s) and/or the lectin specificity.

3.5.3 Crossed Affinoimmunoelectrophoresis of Glycoproteins

Crossed affinoimmunoelectrophoresis (CAIE) combines the interaction between a lectin and glycoproteins in the first-dimension electrophoretic step with crossed electrophoresis into an antibody-containing gel in the second dimension.\textsuperscript{130} This sensitive technique can give important information about the interaction between a given lectin and the glycoprotein to be purified because a good correlation is generally observed between results obtained by CAIE and by affinity chromatography on the immobilized lectin.

Above all, the method rapidly reveals the glycan microheterogeneity of the glycoprotein to be purified. This method can also be used for the characterization of membrane glycoproteins solubilized in nonionic detergents because both lectin–membrane glycoprotein interactions and antigenicity of membrane glycoproteins are not affected by nonionic detergents such as Triton X-100.\textsuperscript{140,141}

Finally, determination of glycan microheterogeneity of serum glycoproteins by CAIE can be used for a rapid and discriminating diagnosis of various pathological conditions.\textsuperscript{142}

4 ISOLATION AND CHARACTERIZATION OF GLYCOPEPTIDES AND GLYCANS

4.1 Proteolytic Digestion of Glycoprotein

In an individual glycoprotein each attachment site frequently accommodates different glycans generating a set of glycoforms. Examination of the glycosylation site heterogeneity requires the proteolysis of the glycoprotein to obtain glycopeptides of different size, which may be HPLC separated or purified and subsequently analyzed by MS. Each individual glycopeptide will contain a unique peptide sequence and a single oligosaccharide chain.

The choice of the protease will determine the number of peptides (or glycopeptides) produced and the length of the peptic chain (directly related to the hydrophobicity of the glycopeptides) and for this reason will considerably influence the choice of the HPLC elution conditions.
4.1.1 Pronase Digestion

Pronase, which is a mixture of endopeptidases with broad specificity, can be used to obtain glycoasparagines or glycopolypeptides with a very short peptide chain. After purification, the structure of the glycan moieties can be established either directly or after their release by chemical or enzymatic methods.

4.1.2 Tryptic and Chymotryptic Digestion

In order to minimize the peptide heterogeneity of the glycopeptide, the enzymes of choice will be the highly specific proteases such as trypsin or chymotrypsin. Proteolytic hydrolysis may be performed either on native glycoproteins or after reduction and alkylation which generally produces a better substrate for protease digestion.

Trypsin, chymotrypsin or endoproteinase Glu C (Staphylococcus aureus V8 protease) are used when a longer polypeptide chain is required or when it appears necessary to access the different glycan structure to each of the glycosylation sites present on the polypeptide chain.

4.2 Methods for Glycan Release

As a detailed structure of individual glycans cannot be achieved directly on the native glycoprotein, for a complete structural study the glycan must be released from the glycoprotein either by chemical or enzymatic hydrolysis.

4.2.1 Chemical Release of Glycans

As previously mentioned, glycans can be covalently linked to the peptidic backbone through O- or N-glycosidic linkages. These two fundamental types of linkages present different susceptibility to alkaline hydrolysis. The O-linkage is easily cleaved in diluted sodium hydroxide solutions (0.05–0.1 M) at 37 °C for 48 h in the so-called β-elimination reaction. Alkaline treatment is generally achieved in the presence of a reductive agent such as sodium borohydride (NaBH₄) in order to avoid further degradation by a peeling reaction of released oligosaccharides. For that reason, O-glycans are released from the glycoprotein as oligosaccharide-alditols.

The N-linkage is quite stable during the β-elimination procedure and N-glycans are released as glycopeptides. Cleavage of N-glycans requires a strong alkaline agent such as hydrazine. The hydrazinolysis procedure is commonly used for releasing N-glycans. This is then a three-step procedure including the hydrazine treatment, the N-re-acylation of hexosamines and sialic acids, and the cleavage of resulting hydrazones. N-Glycans are released as free oligosaccharides, having the di-N-acetyl-chitobiose unit at their reducing end. O-Glycans can be partially released using mild reaction conditions. It should be mentioned that both procedures lead to the destruction of the polypeptide backbone.

4.2.2 Enzymatic Release of Glycans

Release of glycans from N-glycosylproteins can be achieved by two kinds of enzymes, namely endo-N-acetyl-β-D-glucosaminidases and peptide-N-glycosidases.

4.2.2.1 Endo-N-Acetyl-β-D-Glucosaminidases (EC 3.2.1.96; Mannosyl-glycoprotein 1,4-N-Acetamido-deoxy-β-D-glycohydrolases)

This family of enzymes hydrolyses the di-N-acetylchitobiose unit common to all the N-glycans according to Equation (1):

\[
\text{(R)-GlcNAc(β1–4)GlcNAc(β1–N)Asn-(X)}_n \xrightarrow{\text{endo glycanase}} \text{(R)-GlcNAc + GlcNAc-Asn-(X)}_n + \text{oligosaccharide + protein} \quad (1)
\]

- Endo H, isolated from Streptomyces plicatus, and endo F1, from Flavobacterium meningosepticum, hydrolyze both high-mannose-type and hybrid-type glycans. These enzymes represent useful tools to discriminate between high-mannose and lactosaminic-type glycoproteins.
- Endo B, isolated from Sporotrichum dimorphoporum, and endo F2, from Flavobacterium meningosepticum, act both on high-mannose and complex glycans.

Generally glycoproteins are denatured prior to the enzymatic hydrolysis; nevertheless endo-β-N-acetylhexosaminidases are able to deglycosylate native glycoproteins and may be employed for the study of glycan functions inside an individual glycoprotein.

4.2.2.2 Peptide-N-glycosidase (EC 3.5.1.52; Peptide-N¹- (N-acetyl-β-glucosaminy) Asparagine Amidase)

Peptide-N-glycosidase, also called N-glycanase, is able to split the monosaccharide–peptide linkage removing the complete glycan moiety of the molecule (Equation 2):

\[
\text{N-glycosyl-Asn-protein} \xrightarrow{\text{glycanase}} \text{glycan} + \text{Asp-protein} + \text{NH}_3 \quad (2)
\]

The enzyme cleaves all types of glycans and the reaction proceeds unless the peptide part is restricted to the sole asparagine residue. The enzyme is isolated from Flavobacterium meningosepticum (peptide-N-glycosidase F). The enzyme is now cloned and
expressed in *Escherichia coli*. Another peptide-N-glycosidase (peptide-N-glycosidase A) has been isolated from almond emulsin. This enzyme is able to cleave glycans bearing an α-1,3-fucose attached to the first N-acetylglucosamine linked to asparagine as found in plant N-glycosylproteins.

### 4.3 Fractionation of Glycopeptides and Glycans

#### 4.3.1 Use of Immobilized Lectins for Fractionation of Glycopeptides and Oligosaccharides

Even though the purification and fractionation of glycoproteins by lectin affinity chromatography is encumbered with some limitations, this method represents a powerful tool for the fractionation of glycopeptides and glycans. Nonspecific interactions often observed between glycopeptides and immobilized lectins, or strong interactions resulting from the presence on a glycoprotein of a high density of a particular saccharide determinant, are absent or very rare in the case of glycans or glycopeptides. These compounds are thus fractionated on the basis of a true affinity chromatography. Consequently, this implies, even more than in glycoprotein fractionations, a very precise knowledge of the exact specificities of the immobilized lectins to be used. Under these circumstances, it often becomes possible to predict the primary structure of lectin-reactive glycopeptides or glycans.

Many fractionation schemes of glycopeptides or glycans, obtained from soluble or membrane-bound glycoproteins, have been proposed.\(^{95-105,156-159}\)

#### 4.3.1.1 General Comments

Before using a new batch of immobilized lectin or after repeated use of a lectin column which may lead to a decrease in its binding capacity, calibration of the lectin column with well-defined glycopeptides or glycans should be performed. Standard glycopeptides or mixtures of glycopeptides to be fractionated can be \(N\)-[\(^{14}\)C]- or \([\text{\textsuperscript{3}H}]\)-acyetylated\(^{160}\) to help follow the lectin column performance. Standard oligosaccharides or mixtures of glycans to be fractionated, released from glycoproteins or glycopeptides either by chemical or by enzymatic cleavages, can be labeled at the terminal reducing GlcNAc residue by reduction with \([\text{\textsuperscript{3}H}]\)-sodium or potassium borohydride.\(^{161}\)

Most lectin columns equilibrated in PBS containing 0.02% sodium azide can be run at room temperature (20°C) but should be stored at 4°C between consecutive runs. Most lectins are less efficient at 37°C than at room temperature or even at 4°C.\(^{101,115}\) The degree of separation of weakly reactive glycopeptides or glycans may depend on the geometry of the lectin column. A better separation of these compounds is generally obtained with a long and thin column rather than with a wider column containing the same amount of immobilized lectins.

When the exact capacity of a lectin column is not known, the unretained fraction must be recycled on the regenerated column. For example, commercially available Con A–Sepharose\(^{4B}\) from Pharmacia Biotech is able to bind 50–75 µg per milliliter of gel of biantennary \(N\)-glycosylpeptides.

Most immobilized lectins have the same affinity for \(N\)-glycosylpeptides and for glycans released from them either by chemical or enzymatic cleavages. However, \(N-N'\)-diacetyltobitobiose-Asn inner core is an important determinant for binding to immobilized LCA or WGA, and glycans without the asparagine residue or a small peptide sequence do not interact with these immobilized lectins. This is an important point to consider in a fractionation procedure to be used because the discriminating power of an immobilized LCA–or WGA–Sepharose\(^{3M}\) column is considerable and cannot be neglected.

As previously described for glycoproteins, sequential use of immobilized lectins with different and well-defined specificities can fractionate complex mixtures of glycopeptides or glycans into homogeneous families. Generally, lectins with affinity for internal saccharide sequences are used first in the fractionation, whereas immobilized lectins with a specificity towards terminal oligosaccharide-dominant sequences or terminal nonreducing monosaccharides are used later.

#### 4.3.1.2 Fractionation of \(N\)-Glycosylpeptides or Related Glycans on Immobilized Lectins with Affinity for Internal Oligosaccharidic Sequences

*Affinity Chromatography on Immobilized Concanavalin A and Lens culinaris Agglutinin.* Figure 8 presents the structures of \(N\)-glycosylpeptides or related glycans which can be found in the three fractions recovered from an immobilized Con A column as well as in the six fractions resulting from a subsequent affinity chromatography of \(N\)-glycosylpeptides on an LCA–Sepharose\(^{3M}\) column. From this figure, it clearly appears that the α-1,6-linked fucose residue is an important determinant for the binding of \(N\)-glycosylpeptides and that affinity chromatography on immobilized LCA is a valuable tool with which to fractionate glycopeptides into α-1,6-fucosylated and nonfucosylated types. Only \(N\)-glycosylpeptides can be bound on immobilized LCA. So, glycans released from \(N\)-glycosylpeptides either by hydrazinolysis or by enzymatic cleavage are eluted at the void volume of the lectin column.

Immobilized *Vicia faba* and *Pisum sativum* lectins interact also with some α-1,6-fucosylated \(N\)-glycosylpeptides.
Figure 8 Interaction of N-glycosylpeptides with immobilized Con A and LCA (NBF = nonbound fraction, WBF = weakly bound fractions, BF = bound fractions, SBF = strongly bound fractions).
However, their affinity is weaker, so that the fractionation into the two classes is obtained with only the equilibration buffer.

**Affinity Chromatography on Other Lectins with a Specificity for Internal Saccharidic Sequences.** Other immobilized lectins with a specificity for internal saccharidic sequences can also be used to subfractionate N-glycosylpeptide families obtained by affinity chromatography on immobilized Con A and LCA.

As shown in Table 3, *Phaseolus vulgaris* isolecitin E4 (E4-PHA) interacts with bisected bi- and triantennary *N*-acetylactosamine-type glycopeptides or related glycans, and *Phaseolus vulgaris* isolecitin L4 (L4-PHA) interacts with asialolipid- and tetraantennary *N*-acetylactosamine-type glycopeptides or related glycans, containing the dominant pentasaccharidic sequence Gal(β1–4)GlcNAc-(β1–2)[Gal(β1–4)GlcNAc(β1–6)]Man. The two immobilized lectins can be used to subfractionate glycopeptide fractions containing these oligosaccharidic determinants previously isolated by a sequential affinity chromatography on immobilized Con A—and LCA—sepharose. Immobilized WGA can be used to fractionate some hybrid-type N-glycosylpeptides which are bound on a WGA—sepharose column, and to a lesser extent bisected biantennary *N*-acetylactosaminic-type glycopeptides which are only retarded on such a column. Linear poly(4-acetylactosamine) as well as branched poly(N-acetylactosamine)-type glycopeptides or glycans are also recognized with high affinity by immobilized WGA. Immobilized WGA also interacts with glycopeptides having a high density of O-glycosidically linked sialyl oligosaccharides.

4.3.1.3 Fractionation of N-Glycosylpeptides or Related Glycans on Immobilized Lectins with Affinity Directed Towards Terminal Oligosaccharide-Dominant Sequences

**Lectins with a Specificity for Poly(N-acetylactosamine)-type Glycans.** Immobilized pokeweed mitogens, *Lycopersicon esculentum* agglutinin (tomato lectin), or immobilized DSA represent useful tools for the fractionation of *N*-acetylactosamine-type glycans with repeating *N*-acetylactosamine sequences.

**Lectins with a Specificity for Terminal *N*-Acetyllactosamine Sequences.** Immobilized RCA I and RCA II (*Ricinus communis* agglutinin II) present distinct oligosaccharide specificities and the combined use of these two lectins allows the fractionation of *N*-acetyllactosamine-type glycans according to the nature and the linkage of their terminal sugar moieties. Like immobilized RCA I, immobilized RCA II strongly interacts with *N*-acetyllactosamine-type oligosaccharides possessing terminal β1,4-linked galactose residues. However, immobilized RCA II can also strongly interact with *N*-acetyllactosamine-type oligosaccharides containing nonreducing β1,4-linked GalNAc residues. Moreover, whereas immobilized RCA I has a weak affinity for *N*-acetyllactosamine-type oligosaccharides with one or two terminal β1,3-linked galactose residues, immobilized RCA II strongly binds these glycans which can be eluted with a GalNAc solution.

The carbohydrate-binding specificity of four *Erythrina* (E. cristagalli, E. latissima, *E. corallodendron*, *E. lysimon*) lectins is also directed towards unmasked terminal *N*-acetyllactosamine sequences. As for immobilized RCA I, the interaction of *N*-acetyllactosamine-type glycans with immobilized *Erythrina* lectins depends on the number of terminal *N*-acetyllactosamine sequences. The immobilized lectin *Sambucus nigra* agglutinin I (SNA I), isolated from the bark of elder, recognizes oligosaccharides, glycopeptides, or glycoproteins with terminal NeuAc(α2–6)Gal/GalNAc sequences which are bound and can be eluted from the lectin column with a lactose solution. However, asialo derivatives as well as those containing NeuAc(α2–3)Gal/GalNAc sequences do not interact with immobilized SNA I. Immobilized *Maackia amurensis* leukoagglutinin (MAL) binds with high-affinity *N*-acetyllactosamine-type glycopeptides containing terminal NeuAc(α2–3)Gal-(β1–4)GlcNAc sequences. Conversely, asialoglycopeptides as well as glycans with terminal NeuAc(α2–6)Gal-(β1–4)GlcNAc sequences do not interact with the immobilized leukoagglutinin.

Therefore, immobilized MAL and SNA I are two interesting lectins, which can be sequentially used to fractionate sialylated glycans on the basis of their sialic acid linkages and according to the number of sialic acid residues they contain.

4.3.1.4 Subfractionation of N-Glycosylpeptides on Immobilized Lectins with a Specificity Directed Towards Terminal Nonreducing Dominant Monosaccharides

**Lectins Recognizing Nonreducing Mannose Residues.** The immobilized *Galanthus nivalis* agglutinin (GNA), *Narcissus pseudonarcissus* agglutinin (NPA), *Hipppeastrum hybrida* agglutinin (HHA) isolated from snowdrop, daffodil or amaryllis bulbs, as well as...
**Bowringia milbraedi** agglutinin (BMA)(177) isolated from the seeds of the Nigerian legume *Bowringia milbraedi* provide interesting tools for the analysis and fractionation of glycoproteins or glycopeptides containing oligomannosidic-type glycans.

**Lectins Recognizing Terminal Nonreducing N-Acetylgalactosamine and Galactose Residues.** Seeds of *Griffonia simplicifolia* contain five tetrameric isolecitins composed of two subunits A and B. (178) The carbohydrate-binding specificity of the two subunits differs significantly. The A4 tetrameric isolecitin GSA I-A4 recognizes terminal nonreducing α-linked N-acetylgalactosamine residues, whereas the B4 isolecitin (GSA I-B4) has strict specificity towards terminal nonreducing α-galactose residues.

Immobile GSA I isolecitins can be used to isolate either α-Gal-containing glycopeptides(179) or α-GalNAc-containing glycopeptides.(180)

Glycopeptides containing the GalNAc(1–4)GlcNAc sequence in their outer branch moieties bind with high affinity to immobilized *Wisteria floribunda* agglutinin.(181)

**Lectins Recognizing Terminal Nonreducing N-Acetyl Glucosamine Residues.** Immobilized *Griffonia simplicifolia* agglutinin II (GSA II)(182) as well as immobilized *Psathyrella velutina* agglutinin, a lectin isolated from the fruiting bodies of the mushroom *Psathyrella velutina*(183) represent useful tools for the detection and fractionation of glycoproteins, glycopeptides or glycans with terminal nonreducing GlcNAc residues.

**Fucos-binding Lectins.** Immobilized *Lotus tetragonolobus* agglutinin (LTA) displays strong affinity for poly-N-acetyllactosamine-type N-glycosylpeptides containing high amounts of fucose linked α-1,3 to N-acetyllactosamine residues within the linear repeating disaccharide 3-Gal(1–4)GlcNAc(1–3).n (Lewis^a^ antigenic blood group). These glycopeptides are bound to an immobilized LTA column and can be eluted with a fucose solution.(184)

Another immobilized fucose-binding lectin, isolated from fruiting bodies of the mushroom *Aleuria aurantia*, represents a very valuable tool for the resolution of glycopeptides and glycans embellished with different Fuc substituents.(185,186)

**Fractionation of O-Glycosylpeptides Using Immobilized Lectins** A large panel of lectins with well-defined specificities towards oligosaccharidic sequences belonging to N-glycosylproteins is now available for the study of glycan microheterogeneity or for fractionation of N-glycopeptides, glycopeptides, or related glycans. However, very few applications can be found in the literature of similar studies using lectins specifically recognizing O-glycosidically linked glycans.

Nevertheless, by inhibition of hemagglutination or by quantitative precipitation, many lectins were shown to bind to mucin-type oligosaccharides.(175,187)

The carbohydrate-binding specificities of five of these lectins (ABA I (*Agaricus bisporus* agglutinin I), PNA (*Arachis hypogaea* agglutinin), BPA (*Bauhinia purpurea* agglutinin), SBA (soybean agglutinin) from *Glycine max*, and VVA B4 (*Vicia villosa* agglutinin B4)) has been studied by affinity chromatography of mucin-type glycopeptides and related oligosaccharides of known structures.(188)

Another lectin, jacalin, isolated from jackfruit (*Artocarpus integrifolia*) with a high affinity for the T-antigen Gal(1–3)GalNAc(189) represents a useful tool for the analysis and fractionation of glycoproteins containing O-glycosidically linked glycans(190) as well as for the fractionation of O-glycosylpeptides or related oligosaccharide-alditols.(191,192)

**4.3.2 High-performance Liquid Chromatography Separation of Oligosaccharides and Glycopeptides**

**4.3.2.1 Reversed-phase High-performance Liquid Chromatography of Glycopeptides** Fractionation of glycopeptides released by proteolytic cleavage may be performed by hydrophobic binding and reversed-phase chromatography.

Separation of glycopeptides is generally achieved on C18 columns (octadecylsilyl silica) or C8 columns (octasyl silica). The essential criterion responsible for separation is the interaction of the packing with polar materials. Reversed-phase high-performance liquid chromatography (RP-HPLC) will allow separation on the basis of peptide hydrophobicity. Modification of the amino terminus with tyrosine increases this hydrophobicity.(193)

Under some elution conditions the degree of sialylation of glycopeptides can influence the separation. In the general procedure using aqueous solutions or solvents of medium polarity (acetonitrile), the more polar species elute first and then, as the polarity decreases, the tightly bound more hydrophobic species are eluted. When analyzing glycosylation site heterogeneity, an initial separation of glycopeptides according to their peptide structure, but not according to the oligosaccharide(s) structure, is advantageous.(194–196) The site-specific glycopeptides can then be fractionated on the basis of their carbohydrate structure. Glycopeptides separated by RPHPLC may be further studied by MS.

**4.3.2.2 High-performance Liquid Chromatography Separation of Oligosaccharides** As a result of their extreme structural diversity, oligosaccharides isolated
from glycoproteins are complex mixtures often of closely related isomeric compounds. For this reason HPLC has proved to be of great value in oligosaccharide purification because of the wide range of absorbents and solvent systems available as well as the speed of separation. Glycans can be separated according to different structural parameters such as their size, charge, or composition. Some chromatographic systems such as HPAEC (high-pH anion-exchange chromatography) will also be selective for the ring substitution and branching configuration. Some chromatographic systems such as HPAEC (high-pH anion-exchange chromatography) will also be selective for the ring substitution and branching configuration. Some chromatographic systems such as HPAEC (high-pH anion-exchange chromatography) will also be selective for the ring substitution and branching configuration. Some chromatographic systems such as HPAEC (high-pH anion-exchange chromatography) will also be selective for the ring substitution and branching configuration. Some chromatographic systems such as HPAEC (high-pH anion-exchange chromatography) will also be selective for the ring substitution and branching configuration.

**Reversed-phase High-performance Liquid Chromatography of Oligosaccharides.** Separation of neutral oligosaccharides may be achieved at room temperature on C18 octadecyl silane (ODS) RPHPLC columns using either pure water as an eluent or a low acetonitrile concentration (1–5%). As oligosaccharides occur in solution as a mixture of anomers (α, β) a pure oligosaccharide may provide two peaks during the HPLC separation or more generally poorly resolved broad peaks are obtained. Free nonreduced oligosaccharides released from glycoproteins either by hydrazinolysis or endoglycosidases can be derivatized on their reducing group with an amino coproteins either by hydrazinolysis or endoglycosidases obtained. The same hydrophobicity is observed for fucosylated oligosaccharides, which are generally more retained on the column compared with the nonfucosylated form.

If RPHPLC of neutral oligosaccharides is rather limited, separation of derivatized oligosaccharides (pyridylamino, benzoylated) gives a better separation of these compounds according to their molecular size or the nature of constituent monosaccharides (hexosamines, fucose). For these reasons, RPHPLC of derivatized oligosaccharides is used in two-dimensional mapping strategies. These methods are based on parameterization of the contribution of the individual component sugars to the chromatographic behavior of the oligosaccharides. Thus the oligosaccharides are chromatographed on two HPLC columns and their elution volumes are expressed relative to those of standard glucose oligomers.

**Anion-exchange High-performance Liquid Chromatography.**

- Anion-exchange chromatography. Oligosaccharides may be differently charged according to the presence of acidic monosaccharides such as sialic acid, GcNA, or the presence of anionic substituents (sulfate or phosphate groups). Therefore, glycans can be subjected to ion exchange chromatography and separated into neutral, mono- di-, tri-, or tetracharged compounds. Separation of oligosaccharides according to the number of charges generally constitutes the first step in glycan separation. Either strong or weak anion exchangers can be used for the separation of oligosaccharides.

Sialylated and sulfated oligosaccharides can be separated on a Micropak® AXS (30 cm × 4.6 mm) column (Varian) and acidic oligosaccharides have
been separated on a Mono-Q® HR 5/5 (50 cm x 5 mm) column (Pharmacia).\(^{223}\)

- **HPAEC of oligosaccharides.** The recent introduction of HPLC using pellicular ion-exchange resins under high-pH conditions and detection of sugars with pulsed amperometric detection (PAD) has simplified the separation and analysis of both mono- and oligosaccharides.\(^{200,224}\) The method may be used for analytical (i.e. for mapping oligosaccharides released from glycoproteins) or for preparative purposes, when it constitutes the final step in oligosaccharide purification. HPAEC has been applied with success in the separation of glycans originating both from N-glycosylproteins and mucins as well as from glycolipids.\(^{224,225}\) The high resolving power of HPAEC and the high sensitivity of pulsed amperometry detection has allowed for a simple one-step procedure for profiling the total N-linked oligosaccharide released from a glycoprotein by either endoglycosidase digestion or hydrazinolysis. The advantages of HPAEC/PAD are its ability to separate underivatized oligosaccharides and its sensitivity (10 pmol). The high resolution obtained with commercially available columns makes possible the profiling of any given glycoprotein. Isomeric forms differing in only a single linkage or in branch position of one residue may be resolved by HPAEC. The principle of the method lies in the fact that carbohydrates – which are polyhydric compounds – may be considered to be weak acids, thus in basic solution oligosaccharides form negatively charged oxyanions that will interact on strong anion-exchange columns. Predicting the elution order of oligosaccharides is largely empirical because different factors affect the formation of oxyanions, such as the number and nature of the monosaccharides, linkage, branch location, hydrophobicity, or steric conformation. However, the following observations hold:

  - The retention volume increases with the degree of polymerization.
  - Oligosaccharide-alditols have shorter retention times in comparison to nonreduced oligosaccharides.
  - Oligosaccharides with a fucose (α1–6)-linked to the chitobiosyl core elute earlier than non-fucosylated oligosaccharides.
  - Sialylated oligosaccharides with (2–3)-linked NeuAc are more retained than those with (α2–6)-linked NeuAc.
  - Elongation with an additive Gal(β1–4)GlcNAc sequence decreases the retention time.
  - Oligosaccharides with a Gal(β1–3)GlcNAc unit elute later than their counterparts with a Gal(β1–4)GlcNAc sequence.
  - Branching tends to shorten the retention time.

**Adsorption High-performance Liquid Chromatography of Oligosaccharides.**

- **Silica adsorption HPLC.** Adsorption or normal-phase chromatography relies on the surface hydroxyl groups of silica which can interact with solutes, thereby allowing separation according to the different strengths of interactions. This method is generally used for the separation of derivatized oligosaccharides with a low degree of polymerization using nonaqueous eluents.

- **Hydrophobic HPLC on porous graphitized carbon.** These types of columns are now commercially available from Oxford Glycosystems (Glycosep® H). The columns are run in the same eluents as RPHPCL (aqueous/organic solvents in the presence of 0.05% trifluoroacetic acid (TFA)). Separation is based on the interactions of the hydrophobic areas of glycopeptides and oligosaccharides with the carbon surface.\(^{226}\) The method may be used for the separation of derivatized oligosaccharides and provides separation of both neutral and sialyl oligosaccharides.

**Size-partition High-performance Liquid Chromatography of Oligosaccharides.**

- **Ion-suppression Amine-adsorption HPLC.** This method provides for the separation of neutral or negatively charged oligosaccharides, according to their size, on amine columns. Whereas neutral oligosaccharides can be eluted from the column by a linear gradient of acetoni/triethylamine in the mobile phase. This modification of the mobile phase allows oligosaccharides to be eluted in order of size. Nevertheless, it should be mentioned that separations by ion-suppression amine-adsorption HPLC are sensitive to the identity of the anionic moiety, in that oligosaccharides containing (α2–3)-linked sialic acid elute earlier than those containing (α2–6)-linked sialic acid,\(^{227}\) and to the branching pattern.\(^{228}\)

- **Bonded-phase HPLC.** The most frequently used systems for the separation of oligosaccharides are those using chemically bonded phases which fractionate.

---

**Hydrophilic Interactions.** This is based on the interactions of the hydrophilic areas of glycopeptides and oligosaccharides with the carbon surface.\(^{229}\)

**Ion-exchange HPLC.** This is based on the interactions of the charged areas of glycopeptides and oligosaccharides with the carbon surface.\(^{229}\)
material on the basis of their relative affinities for the mobile phase and the bonded phase. Supports containing cyan, diol or aminopropyl\(^{239-242}\) phases may be used. This type of HPLC not only provides size separation of the oligomers, but also of isomers differing in the anomericity or their branching pattern.

- **Gel-permeation HPLC.** Gel-filtration medium-pressure HPLC of oligosaccharides may be realized on noncompressible matrices such as hydroxylated polyether-based matrices (TSK\(^{TM}\)-PW or TSK\(^{TM}\)-HW, from Merck). Nevertheless, the separations are inferior to those currently obtainable by other HPLC techniques and consequently little emphasis is placed here on gel-permeation HPLC of oligosaccharides. This method is generally limited to the desalting of oligosaccharide fractions. However, it should be mentioned that Oxford Glycosystems have developed a method of oligosaccharide analysis based on the sequential degradation by exoglycosidases followed by gel-permeation chromatography of the enzymatic hydrolysate. Each oligosaccharide gives a specific pattern calibrated in glucose units obtained by the reagent array analytical method (RAAM).\(^{234}\)

**High-performance Affinity Chromatography of Oligosaccharides.** The introduction of macroporous silica as a solid support for affinity columns has improved their resolution and shortened their analysis time.\(^{235,236}\) This method is based on weak ligand–ligate interactions at high concentrations of bound ligand on rigid particles approximately 10\(\mu\)m in diameter. Use of monoclonal antibodies\(^{237}\) or lectins as ligands\(^{238}\) allows excellent chromatographic separation of oligosaccharides.

### 4.3.3 Electrophoretic Separation of Glycans and Glycoforms

#### 4.3.3.1 Electrophoretic Separation of Glycans and Glycoforms by Capillary Electrophoresis

During the last years capillary zone electrophoresis (CZE) has become a good alternative and rapid procedure for profiling both glycans and glycoforms.\(^{239-242}\) The procedure is based on the differential migration of solutes through a narrow-bore fused-silica capillary. Charged compounds including sialylated, sulfated, and phosphorylated oligosaccharides migrate in an applied electric field at neutral pH. Neutral sugars can be given a charge by simply adjusting the pH of their environment (high pH), complexation with borate-containing buffers, or conjugation with charged species.\(^{243-246}\)

A major limitation of using CZE for carbohydrate analysis has been the absence of sensitive detection methods. UV detection has been used for both underderivatized and derivatized carbohydrates but it has limited detection sensitivity.\(^{247}\) In contrast, fluorescence detection is easily adapted after conjugation of carbohydrates to different fluorophores, and charged fluorescent tags such as 7-amino-1,3-naphthalene disulfonic acid are commonly used.\(^{248}\) Laser sources are capable of focusing light in small capillaries and thus give increased sensitivity of detection. Detection can also be achieved by PAD.\(^{249}\)

In addition to oligosaccharides, CZE provides efficient separation of glycoforms of a single glycoprotein, according to the occupancy of the different glycosylation sites. This method is routinely used for control of the glycosylation pattern of recombinant glycoproteins.\(^{250-253}\)

#### 4.3.3.2 Fluorophore-assisted Carbohydrate Electrophoresis

Acidic oligosaccharides can be separated by polyacrylamide gel electrophoresis (20–40% slab gels) according to their charge. For that reason, only charged compounds (e.g. those containing sialic acid, uronic acids or charged O-glycans such as sulfate or phosphate groups) can be analyzed by electrophoresis. To overcome this limitation of the FACE technique, reducing oligosaccharides are coupled to negatively charged fluorescent dyes such as 8-amino-naphthalene-1,3,6-trisulfonate, 4-amino-naphthalene sulfonate, or 7-amino-1,3-naphthalene disulfonate.\(^{254-258}\)

Once a carbohydrate has been derivatized with one of these charged fluorescent tags, the carbohydrate molecule will possess an overall net negative charge and therefore will migrate in an electric field. Moreover, the fluorophore provides a high level of detection sensitivity and carbohydrate bands can be visualized under UV (360 nm) or using a commercial imaging system, such as a charge-coupled device (CCD), to quantify the amount of oligosaccharide present in each band. This method permits separation of charged or uncharged oligosaccharides with high resolution and can detect single hydroxyl anomeric differences between mono- and oligosaccharides of sugars with otherwise identical molecular weight charge and sequence. The method can be combined with sequential hydrolysis using specific exoglycosidases in order to assess the structure of isolated glycans.\(^{254}\)

The FACE method is a convenient and rapid procedure largely used in the quality control of recombinant glycoprotein glycosylation.\(^{259,260}\)

### 4.4 Structural Characterization of Glycans

Complete structural analysis of purified glycans requires determination of: (a) the type and number of constituent monosaccharides including their ring form (D or L) and their anomeric linkages (\(\alpha\) or \(\beta\)); (b) the positions of the linkages between individual sugars and their sequence;
Fucosyl residues are typically present on glycans and position of any noncarbohydrate substituents. Several different methods are required to provide all the information. Commonly used methods combined GLC and HPLC chromatographies with physicochemical methods such as MS or NMR.

Monosaccharides commonly found in glycoproteins may be divided into neutral (Man, Gal or Fuc) hexosamines (GalNAc or GlcNAc) and acidic compounds (Neu5Ac or GlcA).

Additive heterogeneity comes from the possible substitution with aglycone residues such as sulfate, phosphate, or acetate groups. Prior to their analysis, monosaccharides have to be released from the oligosaccharide chain by acid hydrolysis. Different methods are available for the analysis of monosaccharides depending mostly on the amount of material available. Several techniques, such as GLC or HPLC, allow both quantitative and qualitative analysis of monosaccharide mixtures. Other chromatographic or electrophoretic procedures just allow a rapid qualitative analysis of samples. Single separated monosaccharides may be further identified by physicochemical methods such as MS or NMR.

### 4.4.1 Release of Monosaccharides

Prior to their analysis, individual monosaccharides have to be released. The way in which individual monosaccharides are released and processed depends on the methods, which will be further used for their analysis. Different hydrolysis procedures using either chlorhydric, sulfuric, trifluoroacetic, or acetic acid may be used. It has to be kept in mind that the susceptibility to acid hydrolysis as well as the stability of the released units is different for each monosaccharide. Mild hydrolysis conditions may be employed to specifically release some sugars as fucose or sialic acids:

- Fucosyl residues are typically present on glycans in nonreducing external terminal positions; it is therefore susceptible to acid hydrolysis under mild conditions using diluted (0.05 M) HCl or TFA solutions.\(^{261}\)
- Mild acid hydrolysis using acetic acid and/or enzymatic release with sialidase is recommended for sialic acid analysis.\(^{262}\) Indeed, sialic acids represent a family of different compounds, differing by the presence of various substituents on the hydroxyl groups, which are rather labile and may be lost during the hydrolysis. The modifications have been shown to affect a wide spectrum of biological phenomena.\(^{263}\) When a GLC approach is taken, methanalysis\(^{264}\) is the method of choice because cleavage of all glycosidic linkages is very effective and less destruction of the monosaccharides is observed than during acid hydrolysis.

Monosaccharides are converted to their methylglycosides. It should be mentioned that N-acetyl groups of the main sugars are completely cleaved, and a re-N-acetylation step should be introduced to reincorporate acetyl groups in hexosamines and sialic acids.

### 4.4.2 Gas–Liquid Chromatographic Analysis of Monosaccharides

GLC is a sensitive analytical technique for monosaccharide composition analysis, allowing detection of subnanomole amounts of carbohydrates. The method provides information on both the nature and the amount of the different monosaccharides.\(^{262,265}\) The most commonly used GLC columns are fused-silica wall-coated capillary columns. Detection may be carried out by flame ionization detection (FID) or the gas chromatograph may be coupled to MS (i.e. GLC/MS). This last method provides a further refinement in identification.

Monosaccharides can also be identified by their specific fragmentation patterns.\(^{266}\) Prior to their analysis, monosaccharides have to be derivatized. Trimethylsilylation of hydroxyl and carboxyl groups is the most widely used method.\(^{267,268}\) If only neutral monosaccharides need to be measured, acid hydrolysis followed by reduction and peracetylation (alditol acetate derivatives) is preferred.\(^{269,270}\)

### 4.4.3 Methylation Analysis

The use of methylation analysis in the structural determination of oligosaccharides represents the most classical method for defining both the substitution pattern of a given compound (in terms of linkage position, terminal sugars, branching points) and the ring size of the different monosaccharides. Methylation procedures differing in the nature of the basic reagent used for proton release have been described.\(^{271–274}\) The steps of the methylation procedure are described in Scheme 2. The sequence is: (a) substitution of the different hydroxyl groups not engaged in the glycosidic linkages by methyl groups in alkaline medium; (b) hydrolysis of the methylated oligosaccharides; (c) substitution of the newly generated hydroxyl groups (previously engaged in the linkage) by another substituent such as acetyl groups; and (d) GLC separation of the different methylated ethers. The positions of methyl groups reflect free hydroxyl groups in the original monosaccharides of the native oligosaccharide, whereas acetyl groups give the position of hydroxyl groups initially engaged in the glycosidic linkages. Partially methylated and acetylated monosaccharides can be identified by GLC according to their retention time and in comparison with standard compounds.\(^{275,276}\) Methylation analysis can be combined with GLC/MS analysis,
and the different methyl ethers identified on the basis of their specific fragmentation patterns obtained by electron ionization mass spectrometry (EIMS) or by chemical ionization mass spectrometry (CIMS).

### 4.4.4 Nuclear Magnetic Resonance Spectroscopy in the Study of Glycans

NMR spectroscopy provides a powerful and non-destructive method for structural study of carbohydrates. It can provide almost complete structural information on the glycan including: (a) the nature of the monosaccharides including the ring size; (b) the linkage anomericity; (c) the linkage position; and (d) the nature and degree of substitution by aglycon groups (e.g. sulfate, phosphate, acetyl). Generally a single $^1$H-NMR analysis is sufficient to assign all the parameters of a known oligosaccharide according to the structural reporter group method developed by Vliegenthart et al.\textsuperscript{[277,278]} The $^1$H-NMR spectra may be divided into three distinct regions, the region between 6 and 4.5 ppm being the most important for establishing the number of monosaccharide units. The coupling constant values enable discrimination between the $\alpha$ and $\beta$ anomericity. The bulk region (3.6–3.2 ppm) is generated by other protons (H-2 to H-5) and cannot generally be interpreted in a conventional one-dimensional analysis. The third region (1–3 ppm) is also very useful for structural determination because it corresponds to axial and equatorial protons of sialic acids as well as acetamido protons from hexosamines. Several bidimensional homo- or heteronuclear correlated spectroscopy procedures provide other types of information concerning the oligosaccharide sequence.\textsuperscript{[279]} The more useful are: (a) the correlation spectroscopy (COSY) experiments which measure the coupling constant $J$ between the different monosaccharides; (b) heteronuclear multi-quantum coherence (HMQC) which allows clear identification of the carbon substitutions; (c) heteronuclear multiple-bond correlation (HMBC) which gives direct access to the monosaccharide sequence; and (d) rotating-frame Overhauser effect spectroscopy (ROESY), which allows identification of short-distance proton interactions. The nuclear Overhauser effect intensities may be easily translated into conformational information.

### 4.4.5 Mass Spectrometry Methods for Structural Analysis of Glycans

The introduction of new techniques such as MALDIMS and electrospray ionization mass spectrometry (ESIMS) has had a considerable impact on the application of MS to carbohydrate research. An MS experiment provides two types of structural information, namely the masses of the intact molecules (molecular ions) and the masses of fragment ions. For oligosaccharides, the structural information from MS is essentially limited to monosaccharide sequence and molecular weight, and only in exceptional cases can glycosidic linkage positions be obtained.

Derivatization of glycans, such as by methylation or coupling to fluorescent dyes, generally increases the signals or may provide specific fragmentation patterns necessary to determine glycosidic linkage positions.\textsuperscript{[280–283]}

#### 4.4.5.1 Fast Atom Bombardment Mass Spectrometry

Although FABMS can be applied to native oligosaccharides, the derivatized compounds (permethylated or peracetylated) are preferred because the sensitivity of the analysis is significantly increased.\textsuperscript{[284–287]} The most important fragmentation observed concerns the cleavage of the glycosidic linkages. In particular, fragment ions are predominantly formed by cleavage of the glycosidic bonds engaged with amino sugars, such as GlcNAc or GalNAc.\textsuperscript{[288]} Even though FABMS is less sensitive than other more modern MS techniques, it remains the method of choice for the determination of the primary structure of glycans.

#### 4.4.5.2 Matrix-assisted Laser Desorption/Ionization Mass Spectrometry

The use of lasers for ionizing carbohydrates has become popular for analysis of both glycans and their glycoconjugates.\textsuperscript{[280,289,290]} In this technique, samples are mixed with a UV-absorbing matrix such as 2,5-dihydroxybenzoic acid (DHB)\textsuperscript{[291]} or 2,4,6-trihydroxyacetophenone (THAP)\textsuperscript{[289]} and are ionized within the mass spectrometer by irradiation with a UV
laser. Spectra are usually examined with a linear time-of-flight (TOF) mass spectrometer, but greatly increased resolution can be obtained with a reflectron-type mass analyzer. The MALDIMS technique can be used for analysis of large molecules such as glycopeptides or intact glycoproteins. The technique is particularly useful for determining the presence or absence of glycosylation in a glycoprotein and may be combined with deglycosylation experiments using exo- or endoglycosidases.

4.4.5.3 Electrospray Ionization Mass Spectrometry

The major application of ESIMS is in the analysis of glycopeptides and glycoproteins which possess multiple charge sites. The method is of particular interest for glycoform study and for determination of the glycosylation site occupancy. Glycopeptides are obtained by proteolytic digestion of the native glycoproteins, separated by HPLC and analyzed by ESIMS. A number of methods have been devised to identify the glycopeptides in such analyses using either specific endoglycosidases or specific daughter ions characteristics of the carbohydrate (e.g. m/z 204 from N-acetylhexosamine) to highlight the glycopeptides peaks. The method can be coupled to microbore liquid chromatography (LC), permitting on-line LC/ESIMS analysis, or to capillary electrophoresis which is useful when complex mixtures of peptides and glycopeptides are being examined (e.g. after proteolytic digestion of a glycoprotein). Free neutral carbohydrates lack a natural charge size and are more difficult to ionize by ESI. However, due to the propensity of carbohydrates to attract sodium, sodium salts can be added to the spray to enhance ionization. Increased sensitivity can be achieved by introduction of a constituent charge, after derivatization of free oligosaccharides with UV or fluorescent dyes by the reductive amination method or other procedures.

5 CONCLUSIONS

The study of the glycosylation pattern of glycoprotein remains an enormous task due to the extreme heterogeneity of the glycans present at each glycosylation site. Physicochemical methods such as MS analyses associated with powerful separation procedures such as HPAEC, CZE, or FACE have made structural studies feasible on very small quantities of material. Improvements to these new methods have enabled the characterization of new types of glycosylation. Structural glycobiology has become part of the “post-genome” program, and the study of glycosylation can no longer be considered independent of protein characterization. New strategies, such as the proteomic approach, propose to study both glycans and peptidic sequences in a single step.

GLYCOPEPTIDE ANALYSIS: GENERAL METHODS

Glycoprotein Analysis: Using Nuclear Magnetic Resonance

Bas R. Leeflang and J.F.G. Vliegenthart
Utrecht University, Utrecht, The Netherlands

1 Introduction

The majority of proteins are decorated with one or more covalently linked carbohydrate chains, and are thus glycoproteins. These carbohydrate chains may consist of mono-, oligo- or polysaccharides, which can affect the physiological behavior and biological functioning of the glycoprotein. Insight into the structural aspects and characteristics of glycoprotein glycosylation is an important step in unraveling the function of carbohydrate chains in a glycoprotein. In most cases the glycan and protein moieties are cleaved and analyzed separately. Nuclear magnetic resonance (NMR) spectroscopy is a powerful tool in this respect. A plethora of NMR techniques are available to obtain NMR parameters such as chemical shift, scalar coupling constants and relaxation and cross-relaxation properties. From these, both primary structural, three-dimensional structural and dynamical features can be determined for these molecules. In this article, several aspects of glycoprotein structural studies will be discussed, and a selection of NMR experiments, including experimental conditions, will be presented.

1 INTRODUCTION

Proteins are among the most important biomolecules. More than 50% of all proteins are decorated with one or more covalently linked carbohydrate chains, and are thus glycoproteins. These carbohydrate chains may consist of mono-, oligo- or polysaccharides, which can affect the physiological behavior and biological functioning of the glycoprotein. Insight into the structural aspects and characteristics of glycoproteins glycosylation is an important step in unraveling the function of carbohydrate chains in a glycoprotein.1–3

Until recently, the NMR analysis of intact glycoproteins was too elaborate and/or too difficult to do. Only in recent years have some glycoprotein NMR studies been presented. In most cases, the structural analysis is subdivided into smaller problems. Initially, the glycan and the protein moieties are cleaved, and analyzed separately. In some cases this is followed by a study of the intact glycoprotein. The cleavage can be achieved enzymatically or chemically. The peptide sequence has to be analyzed also, in cases where it is not yet known. The monosaccharide composition and branching information can be established through chemical means. NMR spectroscopy has proven to be a suitable tool to determine the primary sequence of the glycan in combination with the monosaccharide data. In many studies the analysis was considered complete when the primary glycan structure had been determined. The combination of modern equipment and the desire to gain a fundamental understanding of the structure–function...
relation resulted in more advanced studies. These studies include conformational analysis and spatial structure determination of both the glycan and the protein, as well as of the intact glycoprotein. Insight into the molecular mobility and flexibility is important in order to understand complex functions and interactions, such as molecular recognition processes. Again, NMR spectroscopy is a suitable tool to obtain this information. In this article, several aspects of glycoprotein structural studies will be discussed.

2 SAMPLE PREPARATION

In order to obtain the most information from NMR spectra, the preparation of the samples is of vital importance. Obviously much attention has to be given to the choice of solvent, to solvent conditions and to sample purity. In particular, contamination by protonated molecules should be avoided as much as possible. Depending on the type of NMR equipment, various sample holders are available, ranging from conventional NMR tubes to dedicated low-concentration, low-volume sample holders.

2.1 Solvent

For $^1$H-NMR experiments on carbohydrates, the samples are normally dissolved in deuterium oxide (D$_2$O or D$_2$H$_2$O), a solvent that closely resembles the natural aqueous solution, however, without the characteristic huge amount of protons. In this way, the skeleton carbohydrate protons can readily be observed. In D$_2$O solution all exchangeable protons (–OH and –NH) are nonobservable. Often the exchange of these protons with deuterium atoms is done in advance in one or more D$_2$O-dissolution/lyophilization cycles. However, in some cases one is particularly interested in these labile protons, for instance when glycopeptides or glycoproteins are studied. The amide signals are needed to obtain a complete sequential assignment of the peptide moiety. Furthermore, the observation of carbohydrate hydroxyl signals or amine and amide resonances has definite applications in the field of conformational analysis. In these cases the sample is generally dissolved in an H$_2$O/D$_2$O mixture with a D$_2$O content between 5% and 10%, needed for the deuterium lock system. It should be noted here that for the latter type of experiments the pH plays a crucial role. The chemical exchange of these labile protons is readily catalyzed at a pH above 7. In many cases the pH is adjusted between pH 5.5 and pH 6.5 to ensure a slow exchange. The exchange rate of hydroxyl protons is larger than that of NH-protons. The presence of metal ions (or salts in general) will have a catalytic effect on the labile proton exchange. The occurrence of paramagnetic impurities is harmful to most NMR experiments. Metal ions are conveniently removed from the sample by passing it through a small column of Calix (Bio-Rad$^{tm}$).

2.2 Purification and Desalting

Next to the choice of solvent, a second condition for obtaining good NMR spectra is careful sample preparation. Next to a functional fractionation of the samples using several chromatographic techniques, all proton-containing contaminating substances, such as buffer compounds, must be removed from the samples. Anionic carbohydrates and large oligosaccharides are easily desalted on small (1 cm × 20 cm) gel filtration columns (e.g. Bio-Gel$^{tm}$ P-2, Bio-Rad$^{tm}$) eluted with water. The sample is recovered in the void volume and is ready for D$_2$O exchange after lyophilization. If the sample contains high amounts of acetate, as can be the case after high-pH anion exchange chromatography, the use of 5 mM NH$_4$HCO$_3$ as eluent instead of pure water facilitates the removal of the acetate. Small neutral oligosaccharides can be desalted on a mixed-bed of cation (e.g. AG 50 W, Bio-Rad$^{tm}$) and anion (e.g. AG 1, Bio-Rad$^{tm}$) exchange resins. A recent advance in sample desalting techniques is the introduction of the Hi-trap column (Pharmacia).

2.3 Sample Amounts and Sensitivity

The amount of information that can be obtained by NMR spectroscopy is immense. The technique, however, is rather insensitive compared with other spectroscopic or spectrometric techniques. The first solution is to put a large amount of sample in the NMR instrument. This can be achieved by using high sample concentrations and/or using NMR tubes with a large diameter. Therefore, sensitivity is not a problem in cases where ample amounts of material are available and are soluble. However, in the analysis of released glycoprotein glycans, the total available amounts are often small (nanomolar and micromolar ranges). Using the standard NMR hardware, the best choice is to use special NMR tubes with a thick glass bottom and a glass insert (plunger) on top of the sample. These kind of NMR tubes are often referred to as “Shigemi-tubes”, named after the main manufacturer. The glass has a magnetic susceptibility close to that of water. Consequently, the magnetic field lines are not refracted at the sample–glass interface. The result is that the effective sample volume can be reduced from 500 to 250–300 µL. Therefore, the NMR spectra can be recorded at increased sample concentrations. To reduce the sensitivity problem further, the manufacturers of NMR instruments offer “micro-probes” or “nano-probes”. In comparison with conventional NMR measurements, the
sample volumes are drastically reduced from typically 500 to 150–50 µL, respectively. In this kind of NMR probe the sensitivity gain is achieved by placing the receiver coils much closer to the (smaller) sample. Especially with the nanoprobe technology, NMR spectra of released glycoprotein glycans can be recorded with sample amounts as small as 10 nmol.

3 PRIMARY STRUCTURE

To characterize the primary structure of a glycoprotein, several structural parameters have to be determined: amino acid sequence, type of linkage of the carbohydrate chain to the polypeptide backbone, position of the glycosylation site, and the primary structure of the carbohydrate chain. The amino acid sequence can be obtained in several ways. Thus far, several different glycan–protein linkage types have been identified. N-glyosyl linkages between N-acetylglucosamine and asparagine residues, O-glycosylation of serine and threonine by N-acetylgalactosamine, N-acetylgalactosamine, or fucose residues all occur widely. In the linkage region of proteoglycans, O-glycosylation of serine by xylose is found. Less well known are C-glycosidic linkages that were discovered in recent years. In this article the focus will be mainly on the analysis of N- and O-glycosidic linkages.

3.1 Glycan Characterization

Glycoproteins are rarely single compounds. Even when they are homogeneous in the amino acid sequence, glycoproteins may consist of a family of compounds. This is due to (micro)heterogeneity that may occur in each glycan at each glycosylation site. This feature forms a serious complication in the structure determination of the glycans. Therefore, characterization of a glycoprotein sample often starts with the cleavage of the carbohydrate chains from the intact glycoprotein along chemical or enzymatic routes. N-linked glycans can be split off through hydrazinolysis. Although this technique has often been applied, in general the use of enzymes has to be preferred, because fewer artifacts are introduced. Several different types of enzymes can be taken into consideration for this purpose: first the so-called endo-enzymes that cleave within the N,N-diacyltchitobiase unit. The enzymes belonging to this category have a rather strict specificity, dependent on the glycan structure. The peptide-N-(N-acetyl-β-glucosaminyladhagamine amidase F cleaves the linkage between the first N-acetylgalactosaminyl residue and the amide group of asparagine. Since it is an amidase, it has a very broad specificity. However, PNGase F is almost inactive when fucose is (α 1–3)linked to the first N-acetylglucosamine residue. In that case, PNGase A has to be preferred. Following the enzyme digestion, the cleaved oligosaccharides are purified using several chromatographic steps.

For the O-linked carbohydrate chains, there are no enzymes available that are widely applicable for cleavage of the whole chain. The most generally applicable cleavage reaction is based on the alkaline borohydride treatment. The resulting oligosaccharide alditols are fractionated through chromatography. Instead of splitting the carbohydrate chains from the glycoprotein, glycopeptides can be prepared through digestion of the glycoprotein with proteolytic enzymes. The structure determination of glycan fragments comprises invariably multi-step processes. A first indication of the character of the glycans with regard to molecular size and charge is obtained from the fractionation by different high-performance liquid chromatography (HPLC) techniques. The qualitative and quantitative monosaccharide composition is established after methanolation followed by gas chromatography (GC). The absolute configuration of the monosaccharides is determined after solvolysis of the methyl glycosides with 2-butanol by GC. The molecular masses of oligosaccharides are derived by mass spectrometric techniques such as fast atom bombardment mass spectrometry or matrix-assisted laser desorption/ionization time-of-flight mass spectrometry.

NMR spectroscopy is by far the most informative method for the determination of the glycan structures. For the primary structure, it is the only method that provides all details, comprising types of constituting monosaccharides including ring size and anomeric configuration, position of glycosidic linkages as well as type and position of non-carbohydrate substituents. Since NMR spectroscopy is a nondestructive technique, it is the most obvious first approach in the analysis of unknown glycans. Prior to NMR spectroscopic analysis, the dry samples are dissolved in D$_2$O and lyophilized in order to exchange the hydroxyl and amide protons for deuterium and dissolved finally in 500 µL D$_2$O with a high isotopic purity.

3.2 Structural Reporter Groups

The one-dimensional $^1$H-NMR spectra of glycoprotein-derived glycans in $^2$H$_2$O solutions show that two groups of signals can be distinguished: the so-called bulk signal and the structural reporter group signals. The former contain mainly the nonanomeric protons, present in a rather narrow spectral area, between 3.2 and 3.9 ppm. Owing to overlap this group of resonances can hardly be interpreted in terms of individual protons. The structural reporter group signals are found outside the bulk region. It appears that it is not necessary to assign all $^1$H-NMR signals for a full characterization in terms of a carbohydrate structure.
The exact location of a proton resonance in the spectrum is determined by the average magnetic field experienced by this proton. This local magnetic field depends on the primary structure (i.e. electron distribution), the spatial structure, and the mobility of the structure. The relation between the chemical shift and the structural parameters is very complex, and not easily accessible for theoretical approaches. Prominent structural reporter groups are the signals as summarized in Table 1.

3.3 Protein Characterization

In many cases the amino acid sequence of the glycoprotein is known at the start of the characterization thereof. Therefore, and because it goes beyond the scope of an article on the analysis of glycoproteins by using NMR spectroscopy, this aspect of primary structure analysis will not be discussed here. The glycosylation sites, however, are not always known. Although characterization of the glycans is most conveniently done on free oligosaccharides, for the determination of glycosylation sites another approach must be followed. Instead of splitting the carbohydrate chains from the glycoprotein, glycopeptides can be prepared through digestion of the glycoprotein with proteolytic enzymes.

Depending on the specificity of the enzymes, the peptide parts can vary in length and the mixture of peptides and glycopeptides can be rather complex. Often for one glycosylation site more than one glycopeptide is found. Peptides are characterized by using N-terminus analysis in conjunction with comparison to the complete amino acid sequence. Structure analysis of the glycopeptides provides information on the identity of the glycans and on the position of the glycosylation sites in the polypeptide backbone. The recent finding of a novel glycosylation type, C-glycosylation, complicates the analysis, because this linkage can thus far not be cleaved without destroying the entire glycoprotein.

NMR spectroscopy is nowadays widely used in protein analysis. The incorporation of $^{13}$C, $^{15}$N and $^2$H isotopes in proteins allows very powerful NMR experiments to be performed. Isotope labeling for glycoproteins, however,
is not frequently used as yet. The reason for this is that the common bacterial cell lines used to prepare isotope-labeled proteins do not have the glycosylation machinery that is essential to glycosylate the proteins. This means that the protein may be obtained but without most of all of its glycans, or with a different glycosylation pattern. Furthermore, the native protein folding frequently depends on the presence of glycans. Therefore one cannot be sure whether the labeled protein has adopted the same three-dimensional shape.

3.4 Glycopeptides

Glycopeptides can often be studied as intact molecules. The primary structure characterization of the glycan part is basically identical to that of free glycans. The structural reporter group method can be applied here as well. Although the chemical shifts of the monosaccharide attached to the peptide will be affected, the overall chemical shift profile will be very close to that of the free glycans. Two-dimensional NMR methods, as described in section 4 on spatial structure, can also be applied to determine the final details of the primary structure. Especially in the case of glycopeptides, this approach is very effective, because the structural reporter group approach is only applicable to the glycan moiety and the peptide moiety. Generally, the primary structures of the peptides are known from chemical amino-acid determinations. This means that NMR spectroscopy is merely used here for confirmation, and in the preparation of three-dimensional structure determinations. In most cases, however, glycopeptides are too small to have a defined spatial structure.

4 SPATIAL STRUCTURE

The properties of nuclear spins depend heavily on molecular structure and dynamics. As a consequence, NMR spectra are intrinsically rich in information on these topics. The NMR spectroscopist needs to assign the NMR resonances to individual spins in the molecule. This is a prerequisite for further analysis and extraction of valuable structural information about the molecule under study. The NMR observables used in structure analysis are primarily the nuclear Overhauser effects (NOEs) and three-bond /-coupling constants. Each NOE cross-peak corresponds with a short distance between two protons. Each three-bond coupling provides information on a dihedral angle. When the assignment of many peaks in the NMR spectra has been completed, lists of NOE cross-peaks and/or three-bond coupling constants can be obtained, providing information on interatomic distances and dihedral angles, respectively. This information can be converted into a three-dimensional model, using methods that frequently include force-field calculations.

4.1 Spectrum Assignment

Signal assignment of complex oligosaccharides can partly be done by comparing occurring chemical shifts with data stored in a library of known compounds. This technique uses the structural reporter group method. The comparison can be performed manually or with the aid of computer database programs. Though this method is valuable for characterization purposes, it does not provide sufficient signals assigned for more advanced analysis of the NMR spectra. Furthermore, the application of the structural reporter group method may fail, when a molecule with novel structural properties or with a large complex structure is studied.

Typically, homonuclear correlation type spectra, such as various correlation spectroscopy (COSY) or total correlation spectroscopy (TOCSY) experiments, are needed to assign signals in the bulk area. This kind of correlation spectrum yields spin systems that correspond to monosaccharides or amino acids (or parts thereof). The glycan assignment procedure generally starts from the anomeric proton signal, or any other well-resolved NMR signal. The two-dimensional spectra can be traversed from diagonal peak to diagonal peak via cross-peaks. In this way the resonances in each spin system can be identified.

Homonuclear correlation experiments identify spin systems. They are essential in this respect, but they do not provide sequence information. Mostly nuclear Overhauser effect spectroscopy (NOESY) or rotating frame nuclear Overhauser spectroscopy (ROESY) spectra are used for this purpose. Often the most intense NOESY peak identifies the linkage location. There are, however, several examples known where the most prominent NOESY peak represents a short distance to another proton. Care should be taken here, because NOESY interactions are through-space interactions and the shortest inter-proton distance may be a long-range interaction with respect to the primary structure. An unambiguous method to resolve this problem is the heteronuclear multiple bond coherence spectroscopy (HMBC) experiment, which yields through-bond correlations. This yields cross-peaks between the anomeric carbon and the ring proton of the adjacent sugar residue, and between the anomeric proton and the ring carbon of the adjacent sugar residue. In order to make use of HMBC spectra, the carbon resonances should be assigned as well as the proton resonances. Heteronuclear single quantum coherence spectroscopy (HSQC) or heteronuclear multiple quantum coherence spectroscopy (HMQC) spectra provide one-bond /–/C correlations. In other words they identify chemical bonds between / and /, and thus
provide the link between the assigned proton resonances and the carbon resonances. The HMBC experiment is basically a HMQC experiment tuned at small (1–10 Hz) heteronuclear couplings. Often the one-bond correlations are explicitly filtered out of the spectrum. However, in our laboratory this filter is hardly used, because omitting the filter gives many one-bond correlations that are useful in the assignment process.

4.2 From Nuclear Overhauser Effect Towards Spatial Structure

NOE cross-peak intensities depend strongly, among other parameters, upon inter-proton distances. Often the NOE cross-peak intensities are assumed to be proportional to $r^{-6}$, where $r$ is the inter-proton distance of the protons to which the cross-peaks were assigned. Although this is generally incorrect, a slight modification of this approach provides a decent set of intramolecular distances which are only marginally affected by the spin-diffusion process or multiple spin relaxation effects. This method is called the “initial rate approach”. For the initial rate approach, several NOESY experiments need to be recorded at various mixing times. The cross-peaks need to be integrated. By fitting a polynomial function to these integrals as a function of the mixing time, $t_m$, the slope (initial rate) at $t_m = 0$ can be estimated.

The experimental NOE cross-peaks can be either negative or positive. This depends on the magnetic field (i.e. the Larmor frequency) and the molecular tumbling, expressed in the rotational-correlation time $\tau_c$. For molecules having a $\tau_c$ near the critical value of $\sqrt{5/(2\pi)}$ no NOEs can be measured, and NOESY is not applicable. Small oligosaccharides fall in this category. NOE-like information, however, can also be obtained from ROESY data. Quantification of inter-proton distances from rotating-frame nuclear Overhauser effect (ROE) intensities is more complicated than from NOESY data.

For small molecules, knowledge of a few distances may be enough to build an initial molecular model, although in many cases, one could find contradicting short distances. In these cases, the molecule in solution may occur in two or more significantly different conformations (Figure 1). For larger molecules, such as (glyco)proteins, several hundreds of relevant short distances may be obtained, making it virtually impossible to build a molecular model from scratch manually. Just as with smaller molecules, conflicting short distances may occur due to different conformations, making the problem even more difficult. Several computational approaches have been developed to handle this problem, such as distance geometry and simulated annealing methods, or combinations of both. These methods yield many first approximation molecular models that may represent genuinely different conformations. These models are optimized using a short molecular mechanics or molecular dynamics run.

5 MOLECULAR MOBILITY

To gain insight into the function of oligosaccharides, glycoproteins, peptides or any other biomolecule, the determination of the spatial structure is a prerequisite. X-ray diffraction, NMR spectroscopy and computational methods are available to obtain molecular structures. Knowledge of the structure alone, however, is often not enough, since molecular flexibility is in most cases essential to their function in biochemical processes. NMR not only provides the tools to determine the spatial structure, but the internal molecular flexibility can also be studied. In NMR spectroscopy, molecular motions are reflected in the relaxation behavior of various NMR observables. The way in which NMR parameters, such as chemical shifts and coupling constants, and dipolar interactions, are affected depends on the relative timescale of the molecular motions. Atomic motion results in reduced NOE cross-peak intensities. The theory behind the NMR relaxation processes is well understood and can be used to determine both the molecular conformation and the molecular flexibility.
5.1 Conformation and Flexibility

Valuable NMR parameters for conformational analysis of biomolecules are the proton–proton NOEs or ROEs. They depend strongly on inter-proton distances and on the mobility of the inter-proton vectors. In the standard approach the mobility of all proton–proton vectors is considered to be constant. This is the so-called isotropic approximation. Now the cross-peak intensities are only a function of all inter-proton distances, and the “overall” tumbling rate ($\tau_c$). This approximation is most useful to determine single conformational molecular models. In practice, however, various distinctly different conformations may occur. How these conformations affect the NMR spectra depends upon the timescale on which the conformations interconvert. In the very slow limit, the NMR spectrum will contain duplicate signals for the same nucleus. In this case, the spectrum is like a spectrum recorded for a mixture of molecules. A typical example of this kind of very slow interconversion is the $\alpha/\beta$ anomerization of reducing sugars in neutral, aqueous solution. At the other end of the timescale (faster than 1 ps) conformations change so rapidly that from a NMR point of view only the time-averaged structure can be observed. The rotation of a (hydroxy-)methyl group is a characteristic example of a very fast conformational change. It is the timescale region in between the extremes where most relevant conformational changes occur. NOEs and ROEs are especially sensitive for mobility in the microsecond to nanosecond timescale. In this regime the faster conformational changes happen, such as conformational changes in glycosidic linkages and glycan ring conversion. The NOESY spectra are now best analyzed, taking into account local mobility within the molecule that is faster than the overall tumbling rate. This is generally done with dedicated software, such as the CROSREL program. Two application examples are given.

Conformational changes, however, occur at any timescale. Mostly, the effects can be observed by using $T_1$, $T_2$ and $T_{1p}$ relaxation times. For exchange rates between 1 µs and 1 ns, NMR spectroscopy does not have suitable parameters to judge the mobility. For the remaining exchange rates various NMR techniques are available.

As an example of the use of relaxation rates we would also like to mention the study on the mobilities of the glycan residues attached to Asn-78 of $\alpha$hCG. (100–1000 Hz) between free and bound states can transfer NOEs obtained in the bound state to the free state. Since the line width of the ligand in the bound state is generally larger than that in the free state, and since the ligand must be present in excess, the signals from the free state ligand will dominate the spectrum. The NOE obtained in the bound state, however, is much stronger than that obtained in the free state. This causes the observed NOE peaks to be dominated by the conformation in the bound state. The TRNOE technique has been applied in a study of the binding of oligosaccharides to antibodies and to lectins.

Laser photochemically induced dynamic nuclear polarization is an advanced NMR technique that allows the detection in proteins and glycoproteins of surface exposed side chains of the aromatic amino acid residues tyrosine, tryptophan, and histidine. The

Figure 2 NMR structure of $\alpha$hCG glycoprotein hormone obtained from NOESY data using the XPLOR program. Two well-defined protein regions are displayed on an atomic backbone level. The mobile protein region is represented by a ribbon. The glycan moieties are reduced to the first GlcNAc residues at Asn-52 and Asn-78, and are displayed on an all-atom level.
suitability of the method was demonstrated to study carbohydrate–protein interactions intramolecularly within glycoproteins and intermolecularly for carbohydrate–lectin interactions.\(^{31}\) NMR experiments can be categorized based on the magnetization used or information transfer pathway. First, magnetization can be transferred through chemical bonds via the so-called scalar or \(J\)-coupling. This is the effect that causes the fine-splitting of NMR signals of individual nuclei. NMR spectra based on this route are often used for the assignment of NMR signals, because of the chemical relation between interacting nuclei. Second, magnetization can be transferred through space via cross-relaxation. Cross-relaxation is the effect when relaxation of the spin-state of a nucleus is stimulated by the close presence of one or more other nuclei. NMR spectra based on this route provide information on the spatial structure of the molecule.

6.1 Correlation Spectroscopy\(^ {38,39} \)

The COSY experiment was the first two-dimensional NMR experiment to be proposed and is still used today, although it has several drawbacks. Its strength, however, is that it provides information on proton pairs that are visibly coupled to each other in the one-dimensional NMR spectrum (fine splitting of the signal). With COSY there is no net magnetization transfer, which means that the cross-peaks have a zero integral. Half the multiplet signals are positive, whereas the other half is negative. As long as the \(J\)-coupling is larger than the line width this causes no problems. When the \(J\)-coupling becomes small compared to the line width, the cross-peak magnitude is reduced by the cancellation of the positive and negative multiplet

![Diagram of signal canceling effects in COSY type spectra](image-url)
signals (Figure 3). A second drawback, especially in the field of carbohydrate NMR, is the dispersive character of the diagonal peaks. Because of their long tails, the dispersive signals severely hamper the analysis of cross-peaks close to the diagonal. Preferred alternatives for COSY are double quantum filtered correlation spectroscopy (DQF-COSY) and TOCSY with a short mixing time.

6.4 Total Correlation Spectroscopy

In our laboratory, TOCSY, formerly also called HOHHA (Homonuclear Hartmann Hahn spectroscopy) is the method of choice to assign as many protons as possible. TOCSY with a short mixing time, i.e. 8–16 ms, yielding spectra with approximately the same information content as DQF-COSY spectra would do, although with increased sensitivity. These experiments mostly have intense cross-peaks between the directly coupled protons. Often low-intensity cross-peaks are found, due to the relay of magnetization to the next coupling partner. This serves as an aid in the assignment. Not only the directly coupled proton is found on one track, but also those that are one or more coupling steps further. TOCSY with longer mixing times, typically up to 120 ms, may yield the complete subspectrum of one monosaccharide. The intensity of a TOCSY cross-peak depends on the magnitude of the J-coupling constants and on the mixing time. For Gal and GalNAc, where the coupling constants between H4 and H5 are small (<1.5 Hz), it is virtually impossible to obtain a full subspectrum. In these cases the magnetization transfer from the well-resolved H1 atom reaches the H4 but not the H5. H5, H6 and H6’ could be identified using TQF-COSY in combination with NOESY or ROESY experiments.

TOCSY does not suffer from the cross-peak cancellations when the line width is greater than the J-coupling (Figure 3). Occasionally the fact that TOCSY relays the magnetization over the whole spin system is a drawback. One is not always sure whether a cross-peak is a genuine ‘COSY’ type cross-peak or a RELAY-COSY peak. In these cases we still use a DQF-COSY experiment.

The occurrence of cross-peaks due to NOEs in the rotating frame (ROESY type cross-peaks) is a common artifact in TOCSY spectra. They can be distinguished from the intended TOCSY peaks by their invert sign. This effect is a smaller problem for free oligosaccharides than for larger molecules such as proteins or glycoproteins. The reason for this is that free oligosaccharide ROESY type cross-peaks build up slowly. For large molecules clean-TOCSY is often used, where the ROESY type relaxation is cancelled by NOESY type relaxation.

A second potential problem is the sample heating that may be caused by using intensive radiofrequency power, especially in cases when long mixing times are used. Heating can be detected by a changing lock signal level. In practice, a warming-up period of some 5 min suffices to overcome the effects of sample heating. At the end of this period the most critical shim(s) can be adjusted.

6.4.1 Practical Information

Mixing sequence: MLEV-17. Excitation using a hard 90° pulse and softer pulses (60, 90 and 180° pulses) to obtain a spin-lock field strength of 8–10 kHz. Effective 90° pulse: 25–30 μs. For TOCSY the effective 90° pulse corresponds to the actual 90° pulse. For clean TOCSY the length of the
clean delay should be included in the calculation. In our laboratory the clean delay is set to the same value as the length of the 90° pulse. Thus a 90° pulse of 16.66–20 µs is used. Mixing time: 8–150 ms for small molecules; 8–80 ms for (glyco-)proteins.

6.5 Heteronuclear Single Quantum Coherence Spectroscopy

The HSQC experiment exploits the high sensitivity of protons compared to other nuclei such as 13C and 15N. This experiment yields a correlation spectrum for 1H, 13C and 1H, 15N, respectively, by a double insensitive nuclei enhanced by polarization transfer (INEPT) transfer step. For many years it was difficult to acquire heteronuclear correlation spectra for compounds having a natural abundance of 13C isotopes. The emerging magnetic field gradient techniques have reduced these limitations dramatically. For HSQC the proton signal is detected. With a natural abundance of about 1.1% for 13C, 98.9% of the protons are bound to a 12C atom. This means that 98.9% of the detected signal must be eliminated. Without the use of magnetic field gradients, this could only be achieved by phase-cycling. Phase-cycling is a technique that cancels the unwanted signal by subtraction of free induction decays (FIDs) recorded with different phases of the radiofrequency pulses. Each FID, however, contains the unwanted signal for which the receiver has to be put at lower sensitivity. Furthermore, subtraction cancels the unwanted signal but not the associated noise. Using gradient techniques, the unwanted signal can be eliminated before the acquisition, resulting in a much higher sensitivity and preventing dynamical range problems. A further development in recent years is “sensitivity enhancement”, mostly together with gradient coherence selection. To obtain narrow cross-peaks, normally the absorption mode signal is recorded and the dispersive signal is cancelled by phase cycling. Sensitivity-enhanced spectra allow both the absorption and dispersive mode signals to appear in the FID. In the processing stage these are separated, processed in such a way that an absorption mode spectrum is obtained with a sensitivity enhancement up to 1.41 (√2). The pulse sequence is longer, which allows for some relaxation and consequently loss of intensity. Typical sensitivity enhancements are about 1.3.

6.5.1 Practical Information

Hard 90 and 180° 1H pulses and hard 90 and 180° 13C pulses inversely detected. In order to obtain the shortest 13C pulses the spectrometer is wired such that the output of the amplifier goes directly into the probehead. This wiring scheme prevents radiofrequency power loss in the pre-amplifier circuit, but at the same time prevents detection of the 13C-NMR signals.

Depending on the available hardware, 13C decoupling is possible during acquisition. A composite pulse decoupling scheme such as WALTZ or GARP is mostly used here.

To obtain a higher digital resolution in the indirect dimension, the carrier frequency and the sweep width in the 13C domain may be adjusted, such that some signals are folded back into the spectrum in an empty region.

6.6 Heteronuclear Multiple Quantum Coherence Spectroscopy

The information content of HMQC and HSQC spectra is the same. Both provide a correlation between 1H and an X nucleus, mostly 13C. The differences are hidden in the pulse-sequence. HSQC has more pulses and delays than HMQC and the period between the excitation pulse and the acquisition is longer in the case of HSQC. Therefore, HMQC is the preferred technique in cases where the accuracy of radiofrequency pulse lengths and radiofrequency pulse phases is not considered optimal. This may apply for the older hardware. Also, HMQC may be preferred in cases where T2 relaxation is fast. A disadvantage of HMQC is that the cross-peak line widths are generally larger than those in the HSQC, because there is no proton decoupling in t1.

6.6.1 Practical Information

See HSQC.

6.7 Heteronuclear Multiple Bond Coherence Spectroscopy

The HMBC experiment is very important in unambiguous sequential assignment of carbohydrate residues, through the inter-glycosidic heteronuclear long-range coupling. Experimentally, the HMBC experiment is very similar to the HMQC experiment, where magnetization transfer is tuned to small heteronuclear couplings and the decoupling during acquisition is turned off. In many HMBC experiments the residual one-bond interactions are filtered out. In our laboratory this filter is purposely omitted. The presence of single bond correlations is useful for assignment purposes, because both HMBC and HMQC information are present in the same spectrum.

6.7.1 Practical Information

See HSQC.
6.8 Nuclear Overhauser Enhancement Spectroscopy\(^{(38,41,43)}\)

NMR spectra provide information related to inter-proton distances, and is therefore a valuable tool for structural analysis of carbohydrates, proteins, and glycoproteins. The first application is determination of the primary structure of oligosaccharides and/or proteins. The linkage information cannot be found out unambiguously with NOESY and the observed NOE may be long range. This should be evaluated very carefully. HMBC provides this kind of information unambiguously, but at much lower sensitivity. The second application, where further analysis of NOESY spectra is performed, is the determination of the (average) three-dimensional solution state structure of the molecules under study. NOEs can be used in a modeling study, either directly or by converting them into distance constraints. The sign and magnitude of the NOE do not only depend upon the inter-proton distances, but also on the overall and local mobility expressed in the rotational correlation time (\(\tau_c\)). For large molecules (small \(\tau_c\)), the NOESY cross-peaks have the same sign as the diagonal peaks, whereas for very small molecules the cross-peaks have the opposite sign. Di- and trisaccharides are generally in the area where the sign of the cross-peaks is changing, and can therefore not be analyzed with NOESY. In these cases ROESY experiments are the only alternative.

6.8.1 Practical Information

Only hard 90° proton pulses are needed. Solvent presaturation is normally done using a lower power radiofrequency pulse of 0.75 to 1.5 s. During the NOESY mixing time the solvent can be saturated as well. When the spectrometer is equipped with magnetic field gradients, a purging gradient may be given in the NOE mixing period, otherwise a homo-spoil pulse can be used.

6.9 Rotating Frame Nuclear Overhauser Enhancement Spectroscopy\(^{(38,44)}\)

ROESY experiments yield spectra with cross-peaks of closely spaced protons. In this respect it is pretty much comparable to NOESY, although the experimental conditions differ. In contrast to NOESY, this experiment does not have a sign change depending on the size or mobility of the molecule. The cross-peaks are always negative relative to a positive diagonal. Positive cross-peaks do occur in ROESY spectra. Three possible causes for these phenomena exist. First, with chemical exchange, positive cross-peaks are obtained. Second, spin diffusion can be the cause. The first ROESY transfer inverts the sign of the cross-peak. Propagation via a second ROESY transfer within the same mixing period inverts the sign again, yielding a positive spin diffusion peak. Recording both ROESY and NOESY spectra is a method to analyze spin diffusion. Third, with ROESY being a spin-locking technique like TOCSY, it may suffer from TOCSY transfer, causing positive TOCSY peaks. TOCSY transfer may also give spurious peaks due to TOCSY transfer of cross-peak information to a third proton. Minimization of TOCSY transfer in the experimental phase is important for which several techniques are available, such as transverse ROESY (T-ROESY) and off-resonance ROESY.\(^{(46)}\) Equally important is coping with TOCSY transfer in the analysis phase. The CROSREL program\(^{(17–19)}\) corrects for decreased ROESY cross-peak intensities caused by TOCSY transfer between the protons involved. Relay effects are not considered in this program.

6.9.1 Practical Information

Normally a hard 90° proton pulse is used for excitation. Solvent presaturation is normally done using a low-power radiofrequency pulse of 0.75 to 1.5 s. Spin-locking for conventional ROESY (not T-ROESY or off-resonance ROESY)\(^{(46)}\) is achieved at a field strength of 2–3 kHz (90° pulse corresponding to 125–90 \(\mu\)s). For conventional ROESY the carrier frequency during spin-locking needs to be carefully chosen. This is important to reduce TOCSY artifacts on the one hand, and to obtain meaningful ROESY intensities on the other hand. The tilt angle \(\theta\) of the most distant signal in the spectrum should be larger than 60°. Equation (1) shows the relation between \(\theta\), the spin-lock frequency \(v_0\) and the frequency of the most distant signal, \(v_1\):

\[
\tan(\theta) = \frac{|v_1 - v_0|}{\gamma B_1} = \frac{|v_1 - v_0|}{4P_{90}} \tag{1}
\]

where \(P_{90}\) is the length of the 90° pulse at the spin-locking power in microseconds and \(B_1\) is the magnetic field strength of the radiofrequency pulse.

Carbohydrates, including monosaccharides and sugar alcohols, are widely distributed in nature, being found in plants, animals, and micro-organisms. They occur free, or in glycosidic linkage as polysaccharides or glycoconjugates (glycoproteins and glycolipids). It is important that suitable and sensitive methods are available for the analysis of these sugars, as in many cases only very small (microgram) amounts of material may be available. Polysaccharides and glycoconjugates must first be depolymerized to produce the monosaccharides quantitatively. The total carbohydrate released in these reactions may be determined by spectrophotometric or enzymic procedures.

Numerous separation and detection methods are available to measure the individual sugar components. Paper and thin-layer chromatography were two of the earliest techniques available, giving mainly qualitative values for individual sugar components. Major advances were made first in gas–liquid chromatography (GLC) and then with various types of liquid chromatography (LC) in the separation of individual sugars.

High-performance liquid chromatography (HPLC) and capillary electrophoresis (CE) are now two of the most commonly used techniques in sugar chromatography. Highly sophisticated detection systems, such as mass spectrometry (MS) for gas–liquid chromatographic separations, and spectrophotometric, fluorometric, and electrochemical detection systems for LC of carbohydrates with suitable chromophores or fluorophores have been developed.

Carbohydrates have been derivatized for use either in precolumn or postcolumn chromatography, resulting in the detection limit in the most sensitive systems approaching yoctomole levels for individual sugars.

1 INTRODUCTION

1.1 Monosaccharides

Monosaccharides are classified into triose, tetrose, pentose, hexose, etc. according to the number of carbon atoms in the molecule. Thus xylose (C₅H₁₀O₅) is a pentose, glucose (C₆H₁₂O₆) is a hexose, and rhamnose (C₆H₁₂O₅) is a deoxyhexose.

Monosaccharides are individual monomeric carbohydrate units of polysaccharides or glycoconjugates (glycolipids or glycoproteins) and cannot be hydrolyzed to simpler compounds.

Monosaccharides are polyhydroxy aldehydes (aldoses) or polyhydroxy ketones (ketoses) and, as reducing sugars, exist virtually exclusively as cyclic hemiacetals. Hemiacetals are formed in reactions between carbonyl compounds (aldehydes or ketones) with alcohols, as illustrated in Scheme 1.

\[
\text{H-C} = \text{O} + \text{R-OH} \xrightleftharpoons{\text{OR'}} \text{H-C} - \text{OH}
\]

Scheme 1 Formation of a hemiacetal from an aldehyde and an alcohol.

Crystalline sugars exist in a single form, but in solution, sugars are present in both five-membered (furanose) and six-membered (pyranose) forms. These furanose and pyranose forms themselves each exist in two anomeric forms, \(\alpha\) and \(\beta\) (epimeric at C-1 in the case of aldoses and at C-2 for ketoses). The epimeric forms arise because of the rapid equilibrium between themselves and the intermediate acyclic form. This is illustrated in Scheme 2 for D-glucose (Glc), for which sugar only
extremely small amounts of the furanose forms exist in aqueous solution. These structures can be described in the Haworth projection form. The pyranose ring is formed by reaction of the aldehyde group (carbon atom 1) with the hydroxyl group on carbon atom 5 of the same sugar molecule to form a hemiacetal. The corresponding furanose rings are formed between C-1 and the hydroxyl group on C-4.

Scheme 2 Cyclic and acyclic forms of Glc.

Proof of the structure of Glc, together with the elaboration of the configurational basis for the classification of aldose sugars, arises from the work of Emil Fischer over 100 years ago. The structures of commonly found monosaccharides and the established trivial names, including recommended three-letter abbreviations, of these neutral aldose sugars, are shown in Scheme 3. Sugars may occur with modifications, which may include the introduction of functionalities such as carboxyl (uronic acids), phosphate (sugar phosphates) or acetamido groups, as shown in Scheme 4. The current universal nomenclature for carbohydrates has been published.\(^1\)

1.2 Sugar Alcohols

Sugar alcohols are those compounds obtained when the aldo or keto group of a monosaccharide is reduced to the corresponding hydroxy group. Alternative names for these compounds are polyols, polyalcohols, or polyhydric alcohols. Those sugar alcohols derived from aldoses are referred to as alditols. Alditols are named by changing the
ribitol and meso glycosylamine type, derived from Rib or 2-deoxy-Rib

Nucleosides are naturally occurring compounds of the glycosylamine type, derived from Rib or 2-deoxy-Rib

and a pyrimidine (uracil, cytosine or thymine) or purine base (adenine or guanine); two examples are given in Scheme 6. Those nucleosides containing ribose are derived from ribonucleic acid, and those containing deoxyribose are derived from deoxyribonucleic acid. Nucleotides are phosphate esters of nucleosides, usually containing up to three phosphate groups (nucleotide mono-, di-, and triphosphates).

**Scheme 5** Structures of commonly occurring sugar alcohols.

**Scheme 6** Structures of the nucleosides uridine and guanosine, and UDP-Glucose.

1.3 Nucleosides, Nucleotides and Nucleotide Sugars

Nucleosides are naturally occurring compounds of the glycosylamine type, derived from Rib or 2-deoxy-Rib

and a pyrimidine (uracil, cytosine or thymine) or purine base (adenine or guanine); two examples are given in Scheme 6. Those nucleosides containing ribose are derived from ribonucleic acid, and those containing deoxyribose are derived from deoxyribonucleic acid. Nucleotides are phosphate esters of nucleosides, usually containing up to three phosphate groups (nucleotide mono-, di-, and triphosphates).

**Scheme 5** Structures of commonly occurring sugar alcohols.

**Scheme 6** Structures of the nucleosides uridine and guanosine, and UDP-Glucose.
Nucleotide sugars are formed in enzyme-catalyzed reactions from nucleotide triphosphates and sugar phosphates. In a typical reaction, uridine 5′-(α-D-glucopyranosyl diphosphate) (UDP-Glc) is generated from uridine triphosphate (UTP) and glucose 1-phosphate (Glc 1-P) (Equation 1):

$$\text{UTP} + \text{Glc} 1-\text{P} \rightarrow \text{UDP-Glc} + \text{pyrophosphate} \quad (1)$$

The nucleotide sugars in turn are involved in carbohydrate biosynthetic reactions, when the monosaccharide is transferred to an acceptor molecule which may be a growing chain of a polysaccharide or a growing chain of a glycoprotein. A variety of nucleotide sugars, such as UDP-Glc, adenosine diphosphate D-glucose (ADP-Glc), guanosine diphosphate D-mannose (GDP-Man), thymidine diphosphate L-rhamnose (TDP-Rha), and cytidine diphosphate (CDP)-neuraminic acid are involved in highly specific reactions. For example, in the biosynthesis of sucrose, the glucose residue arises from UDP-Glc, transferred from fructose 6-phosphate (Fru 6-P), but in the biosynthesis of starch the glucose residue arises from ADP-Glc which is transferred to a growing linear chain of glucose residues. Examples of nucleosides, nucleotides and nucleotide sugars are given in Scheme 6.

## 2 OCCURRENCE

### 2.1 Composition

Monosaccharides are not normally found in significant amounts in the free form in either plants, animals or micro-organisms. Instead, they are found in vast abundance in the bound form as components of glycoconjugates (glycoproteins and glycolipids) and as polysaccharides. The most common building blocks for these polymers are the hexoses, hexuronic acids, and pentoses. Hirst proposed that the hexose → uronic acid → pentose transformation occurs at the monosaccharide level. Subsequent incorporation of these sugars into polysaccharides was considered to take place by an unspecified mechanism. The involvement of nucleotide sugars in these transformations was first reported by Cardini et al. who proposed that a cofactor in the conversion of galactose 1-phosphate to Glc 1-P was UDP-Glc. The suggestion that compounds of the UDP-Glc type, i.e. other nucleotide sugars, could be involved in the formation of sugars and their subsequent incorporation into polysaccharides was then made by Buchanan et al.

The polysaccharides are found widely in plant, animal and microbial sources, mainly as either storage materials which can be readily metabolized during growth of the organism (starch, seed galactomannans, glycogen) or as structural materials, such as cellulose in plants, chitin in *Crustacea*. The classification of polysaccharides is now accepted to include examples such as proteoglycans and peptidoglycans, where polysaccharide chains are covalently linked to form sugar–amino acid linkages to proteins and peptides, respectively. Where polysaccharide chains are linked to lipid units, the molecules are referred to as lipopolysaccharides. The number of different monosaccharide residues found in these polysaccharides usually varies from one to three or four. In glycoproteins the protein backbone may contain a variable number of carbohydrate chains, each containing up to 20 sugar residues. In glycolipids, oligosaccharide units are linked to lipid moieties. Glycolipids and glycoproteins are frequently located bound in membranes of organisms, although water-soluble glycoproteins form the major components of animal sera.

The distribution of sugar alcohols covers plant, animal, and microbial sources, but those from plants have probably been studied in greater depth. The discovery of sugar alcohols arose from the desire, over a century ago, to find sweetening agents other than honey or sugar cane. Among the earliest sugar alcohols isolated and characterized were glucitol (sorbitol), galactitol, and mannitol. In higher plants, the main site of sugar alcohol formation is the leaf where they arise as end products of photosynthesis. From the leaf, some of these products are translocated to the root, stem, fruits, and seeds.

### 2.2 Depolymerization

#### 2.2.1 Acid Hydrolysis

In order to determine the composition of any polysaccharide, or glycoconjugate, it is necessary to obtain a quantitative estimation of the sugar constituents after hydrolysis of all glycosidic linkages. These polymers contain a range of sugars having a variety of glycosidic linkages, and the conditions required to achieve total depolymerization vary from one molecule to another. Glycosidic bonds differ in their susceptibility to acid hydrolysis. The rate of release of sugars is dependent on the position and anomeric configuration of the glycosidic linkage as well as on the identity of the monosaccharide. No acid hydrolysis procedure is capable of cleaving every linkage to give a quantitative yield of each monosaccharide. Some prior knowledge of the nature of the monosaccharides and the types of linkages involved help to make a choice.

For instance, the glycosidic linkages of polysaccharides containing monosaccharides in the furanose conformation and in addition keto sugars, are readily hydrolyzed under extremely mild conditions. Fructans are completely depolymerized with 0.1 M oxalic acid at 70°C for 1 h.
Neuraminic acid (sialic acid), a common monosaccharide constituent in animal glycoconjugates, is released quantitatively with 0.05 M sulfuric acid at 80 °C for 1 h, but is completely destroyed on heating in 1 M acid. Successful release of neuraminic acid from serum glycoproteins has also been achieved using 0.025 M trifluoroacetic acid at 120 °C for 2 h. whereas Kdo, a component of many bacterial lipopolysaccharides, is released by 1 M acetic acid at 40 °C for 6 h. For most plant noncellulosic aldose-containing polysaccharides, including glucans, xylans, and galactomannans, conditions of 1 M sulfuric acid at 100 °C for 4–6 h will give complete hydrolysis with minimum loss of sugar, or with 1 M trifluoroacetic acid at 120 °C for 1 h. Cellulose can be hydrolyzed quantitatively, after first dispersing the polysaccharide in 72% sulfuric acid at room temperature followed by dilution to 2 M and heating at 100 °C. Carbohydrates containing uronic acid residues pose different problems, due to the greater resistance to hydrolysis of the uronosyl glucosidic bond. Incomplete hydrolysis results with the production of aldobriouronic acids and poor yields of the monosaccharide components. Improved yields are obtained by the incorporation of a prior hydrolysis step using formic acid.

Amino sugars, such as N-acetyl derivatives, 2-acetamido-2-deoxy-Glc, and 2-acetamido-2-deoxy-Gal, are frequently found as components of glycoconjugates, especially glycoproteins containing N-glycan chains. During acid hydrolysis, N-deacetylation results, and the 2-amino-2-deoxyglycosides are resistant to hydrolysis. For complete depolymerization, treatment with 4 M hydrochloric acid at 100 °C for 6 h is necessary. Minimal degradation occurs if sugars and amino sugars are released from polymeric material as methyl glycosides by heating in methanolic hydrogen chloride.

### 2.2.2 Enzymic Hydrolysis

Hydrolysis of polysaccharides by enzymes is an attractive alternative to acid hydrolysis, because mild conditions of pH and temperature may liberate monosaccharide units in quantitative yield. Normally at least two or more enzymes are necessary to accomplish this. Knowledge of the specificity of the enzymes to be used is necessary in order to ensure complete depolymerization and the absence of any oligosaccharide material. Enzymes hydrolyzing polysaccharide material are classified into two types, the endoglycanases, which hydrolyze internal linkages and cause a rapid decrease in molecular size, and exoglycanases, whose action pattern is to release monosaccharide from the products of the endoglycanase reaction. α-Amylase is a well-characterised endo-α-(1 → 4)-D-glucanase which acts on starch and glycogen in a random manner to release oligosaccharides containing both α-(1 → 4)- and α-(1 → 6)-glucosyl residues. Glucoamylase is an exo-α-(1 → 4)-D-glucosidase which acts by liberating Glc from the terminal nonreducing ends on hydrolysis of both α-(1 → 4) and α-(1 → 6) linkages. In a similar way, inulin has been completely hydrolyzed to fructose and glucose on treatment with a fungal inulinase, whereas β-glucans yield glucose only on treatment with a cellulase preparation, and chitin can be quantitatively converted to 2-acetamido-2-deoxy-Glc with an endo-chitinase and N-acetyl-β-D-glucosaminidase.

### 3 SPECTROPHOTOMETRIC ANALYSIS (COLORIMETRIC ASSAYS)

Many methods have been developed for the measurement of total carbohydrate in polysaccharides and glycoconjugates. These methods are usually nonspecific in relation to the measurement of individual monosaccharides, but generally will measure classes of sugars, such as pentoses, hexoses, uronic acids, deoxy sugars, and amino sugars. Frequently, the reactions are carried out in the presence of strong acid, which results in the hydrolysis of all glycosidic bonds, followed by the dehydration of the respective monosaccharides to furans, or pyrrole derivatives, which then condense with specific reagents to give colored products. A number of methods useful for the measurement of total carbohydrate and alditols are listed in Table 1. The methods are empirical and require calibration with known monosaccharides. It is important to appreciate the specificities of the methods which must be checked for interference by other classes of sugars, noncarbohydrate reducing agents, and protein. Several of the methods have proved suitable for the monitoring of carbohydrate eluates from LC columns.

#### 3.1 Reducing Sugars

The amounts of reducing groups are frequently measured in aqueous extracts of carbohydrates, either before or after acid or enzymic hydrolysis. These assays are not specific for monosaccharides in the presence of reducing oligo or some low-molecular-weight carbohydrates. The most commonly used ones are based on modifications of the alkaline copper sulfate (Somogyi–Nelson reagent), alkaline 3,5-dinitrosalicylic acid, and alkaline 2,2'-bicinchoninate.

#### 3.2 Enzyme Assays

With the general availability of highly purified enzymes of known specificity, many monosaccharides and alditols can be checked for interference by other classes of sugars, noncarbohydrate reducing agents, and protein. Several of the methods have proved suitable for the monitoring of carbohydrate eluates from LC columns.

The usefulness of enzymic techniques arises from the fact that, normally no prior separation from other carbohydrates is required, the reactions are carried out at pH values and temperatures unlikely to cause degradation of other products, and they convert the sugars to stoichiometric amounts of product. Most of the enzymes used in these procedures are commercially available, and those which are not may be readily isolated and purified. The experimental procedures for most of these methods have appeared in published collections. Oxidases and dehydrogenases (oxidoreductases) are used in most of the procedures. Oxidases, which are usually highly specific, acting on only one substrate, require the presence of molecular oxygen and the monosaccharide is converted to the corresponding lactone and hydrogen peroxide. Hydrogen peroxide inhibits the forward reaction going to completion. In a coupled reaction, a second enzyme, usually peroxidase in the presence of an acceptor molecule, is used to destroy the hydrogen peroxide and produce a chromogen (Scheme 7). Whereas Glc oxidase oxidizes

ATP, adenosine triphosphate; G6-PDH, glucose 6-phosphate dehydrogenase; HK, hexokinase; PGI, phosphoglucoisomerase; PMI, phosphomannoisomerase; NADH, reduced nicotinamide adenine dinucleotide; NADPH, reduced nicotinamide adenine dinucleotide phosphate.
Glc at C-1 to produce gluconolactone, Gal oxidase oxidizes Gal at C-6 to produce a C-6 aldehyde. Dehydrogenases require the addition of a cofactor, either nicotinamide adenine dinucleotide (NAD\(^+\)) or nicotinamide adenine dinucleotide phosphate (NADP\(^+\)). On oxidation of the substrate, for example, Fuc by Fuc dehydrogenase, an equimolar amount of cofactor is reduced and from its absorbance at 340 nm, the amount of sugar can be directly determined (Scheme 8).

![Scheme 7 The oxidation of Glc by Glc oxidase.](image)

Dehydrogenases frequently do not demonstrate absolute specificity for a substrate. Instead a number of structurally related monosaccharides may act as substrates. The enzyme Fuc dehydrogenase, purified from pig liver, acts not only on Fuc but also on Ara, L-lyxose, L-xylose, and L-Gal.\(^{63}\) However, the latter sugars are not found commonly in biological extracts in the presence of Fuc. Similarly, Gal, D-Fuc and L-arabinopyranose are oxidized by Gal dehydrogenase.\(^{44,64}\) When Gal and L-arabinose are present in the same sample, for instance in hydrolysates of polysaccharides such as L-arabinomannan, the amount of Gal can be obtained from action of Gal oxidase, an enzyme with specificity only for Gal, and the amount of Gal plus L-arabinose can be obtained from the action of Gal dehydrogenase.

Mixtures of the monosaccharides Glc, Fru and Man have been measured following the sequential addition of enzymes (Scheme 9).\(^ {49} \) All three monosaccharides are converted to the corresponding monosaccharide 6-phosphates by HK in the presence of ATP. G6-PDH is absolutely specific for the conversion of glucose 6-phosphate (Glc 6-P) to 6-phosphogluconate and NADPH. Sequential additions of PGI and PMI convert the corresponding Fru 6-P and mannose 6-phosphate (Man 6-P) to Glc 6-P, then to additional amounts of NADPH.

![Scheme 9 The sequential enzymic determination of Glc, Fru, and Man.](image)

Much of carbohydrate analysis depends on the chromatographic separation and identification of these simple sugars, which themselves may have been isolated from polysaccharides or glycoconjugates.\(^ {65–68} \) From the earliest reports on the separation of sugars by paper chromatography (PC), the investigator now has the choice of a large number of techniques which, in chronological order, include thin-layer chromatography (TLC), GLC, LC, including HPLC, and electrophoretic techniques such as paper electrophoresis (PE) and CE.

The PC and TLC techniques, which are generally used as qualitative measures, are the least sensitive methods for the detection of carbohydrates, and require little outlay in equipment costs. The HPLC and CE techniques, when used with detection systems such as laser-induced fluorescence (LIF) of fluorescein derivatives, give the most sensitive detection, but require considerable outlay in capital equipment and running costs. The choice of technique to be used will depend greatly, among other things, on the number of samples routinely required for analysis and the amount of material available for the individual analyses. In the analysis of complex carbohydrates associated with glycoconjugates, 50–300 ng of a mixture of oligosaccharides containing up to six different monosaccharides may be available on release from a typical glycoprotein.\(^ {69} \) Currently, the most sensitive system used for the analysis of carbohydrates will use either HPLC or CE. Most carbohydrates are nonchromogenic, and this results in decreased sensitivity in ultraviolet (UV) or refractive index detection. Since the late 1980s, significant advances have been made both in separation and detection methods. This has been achieved by derivatization of the sugars to allow spectrophotometric analysis to be used in the detection systems.\(^ {70} \) These derivatives,
after separation, may now allow detection of sugars down
to as little as 100 pmol (1 × 10⁻²⁴ mol) in the case of LIF
of fluorescein derivatives.⁷¹

4.1 Paper Chromatography and Thin-layer
Chromatography

The procedures to be used for the separation of
sugars by PC and TLC have been well-documented and
reviewed.⁶⁰,⁶⁷,⁷² Sample preparation is crucial, because inorganic ions, proteins and lipid materials cause inter-
ference with many of the organic solvent mixtures used
in the separations. The procedures for TLC are gener-
ally superior to PC, because of faster separation times,
a greater variety of supports, and increased sensitivity of
detection. Microcrystalline cellulose, which has a similar
capacity for resolution of sugars as does PC, is commonly
used as the supporting material, although alternative sys-
tems using inorganic supports, such as silica gel, are used.
Resolution, in this latter case, depends on both partition
and adsorption effects. The addition of inorganic salts has
been shown to improve the chromatographic behavior in
many of the sugar separations on silica gel.⁷³–⁷⁵.

For the resolution of mixtures of nucleotides and
nucleotide sugars, an anion-exchange form of TLC using
thin layers of poly(ethyleneimine) cellulose has been
used.⁷⁶ Sugars form borate complexes, and these sugar
complexes have been used in the separation of glucose,
mannose and galactose-containing nucleotides of the
same purine or pyrimidine base.⁷⁷

Most of the solvent systems used in PC and TLC for
the separation of monosaccharides can be used for the
separation of sugar alcohols,⁷⁶ but distinction between
these two groups may be difficult due to the similar R₁ val-
ues, although Kremer⁷⁸ has developed a solvent system
for the complete separation of the common monosaccha-
drides and sugar alcohols by TLC, and Han and Robyt⁷⁹
have reported the separation of seven aldoses and their
corresponding alditols. Alditols and some aldoses have
been separated on O-(carboxymethyl) cellulose paper
in the lanthanum, calcium and barium forms.⁸⁰ The TLC
methodology lends itself readily to multiple develop-
ment on chromatographic plates, and new supports have
allowed the automated multiple development of high-performance thin-layer chromatography (HPTLC)
analysis of sugars on hydrophilic layers.⁸¹ A variety
of monosaccharides, including pentoses, hexoses, hept-
uloses, deoxy-sugars, and acetalmidodeoxyhexose, have
been resolved on aminopropyl bonded silica plates in
70% acetonitrile.⁸²

After chromatographic separation of sugars or sugar
alcohols, it is customary to dip papers in reagents such as
silver nitrate, anisidine–phthalate or periodate–pentane-
2,4-dione.⁶⁰ Similar reagents, usually as sprays, are used
for detection of these compounds on TLC plates. Some
extremely sensitive detection methods have been devel-
oped. Reaction of aldoses with 4′,N,N-dimethyl-aminoo-
4-azobenzene 1-sulfonyl hydrazine produces strongly
chromophoric dabsylhydrazone derivatives which allow
detection of 100 pmol of sugar.⁸³ Most aldoses, ketoses,
uronic acids and amino sugars have been detected at levels
as low as 250 pmol by fluorometric detection after treat-
ment with a malonamide spray.⁸⁴ Amino sugars have
been converted to the corresponding fluorescent dansyl
derivatives before TLC separation.⁸⁵ Separated amino
sugars on treatment with fluorescamine at pH 9.0 give
highly fluorescent pyrrolines,⁸⁶ and nanogram amounts
of sugars, sugar acids, lactones and polyols have been
quantified after separation on HPTLC plates following
further with 2,7-dichlorofluorescein.⁸⁷

Nucleotides and nucleotide sugars do not normally
require reagents for detection as they are conveniently
detected after chromatography by examination of plates
or papers under UV light.

4.2 Gas–Liquid Chromatography

GLC is widely used for the quantitative determination
of monosaccharides, sugar alcohols and those compo-
nents that have been derived by hydrolysis of polysac-
charides and glycoconjugates. For polysaccharides and
glycoconjugates polymerization to the correspond-
ing monomers is necessary prior to GLC (section 2.2).
Total depolymerization frequently requires treatments
with mineral acids. A major difficulty is the decompo-
sition of the liberated monomers, if drastic conditions
are necessary in order to hydrolyze the more resistant
glycosidic bonds. Complete hydrolysis of polymeric car-
bohydrates with methanolic hydrochloric acid has been
shown to give higher recoveries of both neutral sugars
and uronic acids.⁸⁸

Simple sugars are polar and nonvolatile. Therefore, for use in monosaccharide analysis, derivatization is the necessary first step, in order to increase the volatility of the sugars. The most popular methods are the formation of alditol acetates, and trimethylsilyl ethers. Trifluoroacetates and aldonitrile acetates have also been used. Some of the common derivatives of sugars used in GLC are listed in Table 3. A single monosaccharide may produce several products on derivatization because in aqueous solution aldoses and ketoses exist in a dynamic equilibrium between the two ring (pyranose and furanose) and acyclic forms. Unless the anomeric center, at C-1 for aldoses and C-2 for ketoses, is destroyed, for example by reduction to the corresponding alditols, up to four multiple peaks (two from the α- and β-pyranose forms and two from the corresponding furanose forms) may appear on the chromatograms. Although the production of multiple peaks on GLC will result in a complex chromatogram, the high efficiency provided by capillary columns usually gives satisfactory separations. Reduction of aldoses or ketoses with sodium borohydride or sodium borodeuteride eliminates the anomeric centers to produce alditols which are readily converted to stable acetates. One of the limitations in using this system for the production of alditol acetates is that carboxyl groups, as in hexuronic acids, are not derivatized, and therefore these sugars do not produce chromatographic peaks. For polysaccharides, such as red-algal galactans, containing quantities of 3,6-anhydrogalactosyl residues, which are rapidly destroyed under harsh acidic conditions, a procedure has been developed to generate stable 3,6-anhydrogalactitol acetate, as an acid-stable 4-methylmorpholine-borane. Several methodological changes, aimed at a simplification of the original alditol acetate derivatization method, have been reviewed.

Other common derivatives, such as trimethylsilyl and trimethylacetyl, have simple work-up procedures, but both derivatives are unstable in the presence of moisture, making decomposition on storage a major problem. In the aldonitrile procedure, aldoses are reacted with hydroxylamine to produce the corresponding oximes. Acetylation of the aldoximes results in the dehydration of the oxime to a nitrile, and acetylation of all of the hydroxyl groups. Although the anomeric centers of the aldoses have been eliminated, thus giving simpler chromatograms, contaminating peaks arising from interaction between the hydroxylamine and acetylation reagents have been reported. In the production of O-methyloxime acetates from aldoses, the original anomeric center is destroyed by the reaction with O-methyl hydroxylamine, but a new one is generated with the production of two products (the syn and anti isomers); this results in the production of multiple peaks on chromatograms.

In addition to the GLC of simple monosaccharides and alditols, as described above, there is a major interest in the separation of partially methylated monosaccharides and their derivatives. This arises from well-established techniques for sugar linkage analysis of glycosidically-linked carbohydrates using methylation and other techniques. Methylation analysis is the most commonly used procedure for linkage analysis, being based on the complete etherification of all free hydroxyl groups on carbohydrate oligomers or polymers. Those hydroxyl groups involved in inter-sugar glycosidic linkages, or which bear other constituents, are not involved in the methylation process. On subsequent hydrolysis of the carbohydrates, partially methylated aldoses are converted, after reduction and peracetylation, to a partially methylated alditol acetate (PMAA), prior to separation by GLC. In early reports, using this technique, monosaccharide derivatives were identified on the basis of their retention times, against standard PMAA derivatives. With the resolving power of GLC coupled with the use of MS, it is possible to determine the positions of glycosidic attachment of monosaccharide units in a carbohydrate polymer, as well as identifying the ring form (pyranose or furanose) of each of the component sugars. The mass spectra of these derivatives give characteristic fragmentation patterns, thus allowing identification of the original monomers and the nature of the glycosidic linkages. Under electron-impact/mass spectrometry (EI/MS), the fragmentation of PMAA is orderly, predictable, and easy to interpret. It is not possible to distinguish stereoisomers by differences in their mass spectra while using EI/MS, but in most instances they can be distinguished by their GLC retention times. Certain pairs of methylated sugars will yield alditols with the same substitution pattern (for example 2,3- and 3,4-O-methylpentose). They will be inseparable by GLC, but if the reduction at C-1 is carried out with sodium borodeuteride, the resulting MS patterns for these sugars will be distinguishable by relevant isotopic shifts in primary fragment ions. Deuterium labeling has also been used in the identification of uronic acid residues in polymers. In order to overcome the well-known problem of the resistance to hydrolysis of glycosiduronic acids, reduction of the carboxyl group with sodium borodeuteride allows incorporation of deuterium atoms into the molecule (−CO₂H → −CD₂OH) to give the corresponding labeled aldose. Those hexose derivatives formed from the uronic acid may then be identified by MS.

Chemical ionization/mass spectrometry (CI/MS) has also been used to identify PMAAs after GLC. A number of gases, including methane, isobutane, and helium have been used in CI/MS procedures, but probably...
the most popular one is ammonia. In general, a superiority in sensitivity of chemical ionization (CI) detection over electron impact (EI) detection is observed. An ion-trap type of detector has been recommended for PMAA analysis. By using micro-scale methylation analysis, as little as 5–10 µg of glycoconjugate may allow complete analysis when using a multiple selection-ion monitoring system, which is reported to be about seven times more sensitive than standard GLC/MS.

4.3 Liquid Chromatography

For many years, until about 1980, LC for the analytical separation of carbohydrates was conducted on low-pressure systems, usually with an anionic resin as a support. However, advances in the design of supports, pumping systems and detection systems have resulted in a variety of new methods, including HPLC, high-performance anion-exchange chromatography (HPAEC), ligand-exchange chromatography (LEC), and hydrophobic interaction chromatography (HIC). The major differences achieved with these methods have been that the length of time required to separate simple monosaccharides has been reduced from several hours to several minutes. The improvements in the design of either precolumn or postcolumn derivatization of the carbohydrates with the corresponding detector systems has resulted in the original detection limits of nanomoles of monosaccharides being decreased to femtomoles or even lower. A general strategy for the chromatographic separation and monosaccharide composition of polysaccharides and glycoconjugates may include LEC and HPAEC in combination with pulsed amperometric detection (PAD), refractive index, or UV monitoring. The identification of monosaccharides can be achieved on-line by coupling liquid chromatography/mass spectrometry (LC/MS).

4.3.1 Anion-exchange Chromatography

Using low-pressure systems, separations of monosaccharides as their borate complexes were achieved by Khym and Zyll, and modifications to the system, involving fully automatic analysis of neutral monosaccharides and oligosaccharides on quaternary ammonium ion-exchange resins have been reported. Hough et al. used a borate–chloride gradient to separate monosaccharides and polyols. As uronic acids are already charged, they can be separated on anion-exchange resins, in the absence of borate ions. A wide variety of aldoses, ketoses, alditols, cyclitols and oligosaccharides have been measured in the effluents from borate anion-exchange columns after periodate oxidation. Mixtures of monosaccharides and alditols have been successfully separated on anion-exchange resins in the molybdate form and postcolumn detection using cysteine–H₂SO₄ and periodate oxidation detected reducing sugars and alditols, respectively.

By far the most common method currently used for the analytical separation of monosaccharides, alditols and nucleotide sugars is HPAEC. This became possible with the development of quaternary-ammonium-bonded pellicular resins stable to operating conditions of high pH. The spherical pellicular resins contribute to the high resolution of the technique by locating all of the ionic groups on the surface, which results in low diffusion. Carbohydrates, in the form of polyhydric molecules, behave as weak acids, having pKₐ values of 12–14. Thus in basic solutions all monosaccharides, and even oligosaccharides, are negatively charged oxy anions. With increasing hydroxide concentration, several of the hydroxyl groups become ionized, with the C-2 being the most acidic. As the mutarotation of sugars is very rapid at high pH, individual anomeric forms of monosaccharides are no longer resolved. The resulting oxy anions can be chromatographed as anions, without prederivatization, with each monosaccharide yielding a single peak. The elution order of monosaccharides correlates with their pKₐ values, and excellent separations have been obtained for neutral, amino-, and acidic monosaccharides derived from hydrolysis of many glycoconjugates, as well as for the determination of polyols in food products. Detection of the eluted sugars may be made by PAD, where sensitivities in the low picomole range can be achieved without derivatization. In this system, the carbohydrates are oxidized at the surface of a gold electrode. The resulting gold oxide layer is converted back to native gold on reversing the voltage on the electrode, and the potential is cycled back to the analytical voltage. The method is rapid and highly sensitive, with less than 1 nmol required for a typical monosaccharide separation.

Amino acids and peptides arising from the hydrolysis of glycoproteins can cause fouling at the working electrode surface. A guard column and a newly developed separator have been designed to eliminate most of this interference.

Alternative electrodes, based on nickel–copper, nickel–chromium, and silver, have been developed for the detection of monosaccharides and sugar alcohols following HPAEC. The separation and PAD of carbohydrates and alditols are improved by the addition to the alkaline mobile phase of barium and strontium ions. Peak symmetry and column efficiency are improved and significant enhancement of the response of the analytes in PAD at the gold working electrode are observed. These findings have been explained in terms of a rapid formation of adducts between polyhydroxy compounds and these divalent nonelectroactive...
4.3.2 Ligand-exchange Chromatography

LEC on microparticulate cation-exchange resins in metal ion forms has been applied to the separation of carbohydrates. Although mainly applicable for the separation of oligosaccharides, the technique will allow separations of monosaccharides and alditols. The ability of neutral sugars to form complexes with metal ions coordinated to cation-exchange resins was demonstrated by Jones et al. For LEC, the metal ions (usually Ca$^{2+}$, Ag$^{2+}$, or Pb$^{2+}$) are electrostatically immobilized on a strong cation exchanger. Water molecules bind to the metal ion, in relation to its coordination number and, when a mixture of carbohydrates is introduced into the mobile phase, they will displace some of the bound water molecules, forming a donor–acceptor complex. Parameters such as carbohydrate structure, choice of metal ion, temperature, and additives to the mobile phase will affect the stability constants of carbohydrates and thus separation. Separations of pentoses, hexoses and their corresponding alditols have been reported in a study using seven different cations. Good resolution of alditols had originally been achieved on cation-exchange resins in the Ba, Ca, and Li forms. In a detailed study on the chromatography of 14 different alditols, effective separations were obtained with cation-exchange resin in its La form, using water as the eluant. On sulfonated polystyrene residues in the europium(III) form with sodium hydroxide as the mobile phase, monosaccharides and alditols have longer retention times than oligosaccharides, whereas monosaccharides and alditols are selectively retained by the resin in the iron(III) form.

4.3.3 Reversed-phase Liquid Chromatography

Reversed-phase liquid chromatography (RPLC) has been applied successfully to both small and large carbohydrate molecules. In this type of chromatography, nonpolar moieties of the solute and the stationary phase undergo noncovalent association in hydro-organic media. The stationary phase is a highly nonpolar surface of a solid support having covalently bound alkyl or aryl chains at the surface. Retention of carbohydrate species requires an interaction between two nonpolar groups, the nonpolar ligand bound to the surface of the solid support of the column, and the hydrophobic moiety of the solute. Basic theoretical concepts of RPLC have been the subject of several reviews. Nonpolar stationary phases are used, usually consisting of microparticulate silica supports with covalently bound alkyl or aryl functional groups at the surface. The most widely used stationary phases include octadecyl (C$_{18}$)-, octyl (C$_{8}$)-, and butyl (C$_{4}$)-coated sorbents. Underivatized carbohydrates are usually chromatographed using water as the mobile phase, but in general, monosaccharides which elute first are not resolved from one another. Precolumn derivatization schemes have been widely exploited for the RPLC analysis of carbohydrates. The choice of type of derivative is usually made to introduce a chromophoric group onto the saccharides to aid detection of the separated molecules. Many of the chromophores are themselves hydrophobic and the conjugates are then readily separated by RPLC. Several reviews on precolumn derivatization have been published. Chromophoric groups are covalently attached either to the carbonyl function of the monosaccharide or, less frequently, to hydroxyl or amino groups. In modifications involving the carbonyl groups, coupling is usually with amines to form imines (Schiff bases) or their more stable products by reductive amination using sodium cyanoborohydride to give substituted amines (Scheme 10). The derivatization reactions that have been developed are well-defined, quantitative, and nondestructive (when used on oligosaccharides). Excess reagents and byproducts produced during the reactions have to be removed prior to chromatography, and the introduced chemical groups must be stable. 

Scheme 10 Derivatization of aldoses by reductive amination.

The analysis of carbohydrates is hampered by the lack of chromophoric or fluorophoric functional groups. Many high-resolution separative techniques, such as HPLC, CE, and fluorophore-assisted carbohydrate electrophoresis (FACE), are not feasible without pre- or postcolumn derivatization of the carbohydrate. Introduction of a simple chromophore or fluorophore as a label at the reducing end, using the reductive amination technique, allows quantitation on a molar basis. The structures of a variety of primary amines and other selected molecules used for these applications are shown in Scheme 11.

Derivatization of aldoses in a two-step reaction via Scheme 12. An intermediate glycamine or 1-amino-1-deoxyalditol is first formed, on interaction of the reducing monosaccharide with the ammonium ion and sodium cyanoborohydride. The glycamine is subsequently derivatized with, for example, PITC to produce a phenylthiocarbamyl derivative, or with α-phthalaldehyde.

4.3.4 Ion-pair Reversed-phase Liquid Chromatography

Ion-pair RPLC has been widely used for the separation of a number of acidic oligosaccharides but, under suitable conditions, the technique may be applied to the separation of simple sugars, sugar acids and amino sugars. Carbohydrates that are weakly acidic and exist as anions in strongly alkaline mobile phases can be separated as ion pairs on addition of hydrophobic quaternary ammonium counter-ions to the mobile phases and using polymeric stationary phases. Nucleotides and nucleotide sugars have also been separated using this technique. Tetrabutylammonium hydrogen sulfate, which is very hydrophobic, was used as a counter-ion. The method allows the direct separation and detection of the 4′-epimeric-uridine 5′-diphosphate sugars (UDP-Gal and UDP-Glc) down to 40 pmol.

**Scheme 12** Derivatization of aldoses in a two-step reaction via the glycamine (1-amino-1-deoxy) derivative.

4.3.5 Hydrophilic Liquid-interaction Chromatography

Chromatography, involving the use of a polar stationary phase with a less polar mobile phase was originally termed normal-phase partition chromatography. Alpert has proposed the term hydrophilic interaction chromatography (HILIC), when applied to chromatography driven by polar forces. This then differentiates normal-phase partition chromatography from reversed-phase (hydrophobic) chromatography. Recent progress in HILIC has been published. The stationary phases commonly used in HILIC are of the microparticulate and macroporous silica type, having average particle diameters of 3–5 µm, and also sorbents in which polar phases are chemically bonded to silica gel. A few synthetic polymer supports containing chemically bonded polar phases are also available. Some examples of these stationary phases and the types of sugars capable of separation on them are given in Table 5.

Detection systems used in earlier work on HILIC involved the use of refractive index detectors, which were relatively insensitive and their sensitivity to changes in solvent composition, in the case of gradient elution with organic solvents, limited their use.

Although in the case of isocratic elution the detection limit is below 25 ng for sugars, evaporative light-scattering detectors give superior sensitivity. Pre-column derivatization to introduce chromophoric or fluorescent groups into monosaccharides oralditols (Table 4) is now widely used to increase the sensitivity of detection. Some postcolumn derivatization methods suitable for HILIC are described in the following section.

4.3.5.1 Postcolumn Derivatization Methods

In LC, post-column derivatization plays an important role in the automation of carbohydrate analysis. The mobile phase is constantly eluted from the solid-phase column, on which the separation is achieved. By continuously mixing a flow of reagent solution into this eluant, followed by reaction
for an appropriate length of time, and at an appropriate temperature, the separated components of the sample are converted to derivatives that are successively monitored at a detector.

Some of the earliest methods to be used in the post-column detection of carbohydrates include those methods in which carbohydrates including mono-, oligo-, and polysaccharides, are converted to furfurals in the presence of strong acids, which are condensed with chromogenic reagents, such as phenol, orcinol, cysteine, anthrone, resorcinol, and carbazole. Those methods listed in Table 1 that were originally designed for manual operations in detecting carbohydrates,23–32 have been modified for automatic analyzers.184 The major drawback in the use of such reagents is that they require the use of corrosive strong acids.

In order to eliminate methods requiring the use of corrosive acids, a large number of photometric, fluorimetric and electrochemical methods have been developed for postcolumn detection of monosaccharides and alditols following LC.41 A wide range of reagents and methods, some of which are listed in Table 6,40,185–194 are now available for the detection of sugars. A well-recognized property of reducing sugars is their ability to reduce solutions of salts of copper(II) to copper(I).41 Addition of chelating agents such as 2,2'-bicinchoninate or bis(phenanthroline) form chelates with the copper(I) ion, which in the former case can be measured photometrically185 and in the latter case electrochemically.186

Alditols cannot be detected with these reagents because they possess no reducing properties. The usual procedure for the detection of alditols involves periodate oxidation of the samples to release formaldehyde, followed by the Hantzsch reaction to produce pyridine derivatives for photometric or fluorimetric detection. The two-step reaction involves, first the quantitative liberation of formaldehyde on periodate oxidation of the CHOH–CH2OH or –CO–CH2OH groups (Scheme 13a) followed by the condensation of the formaldehyde with pentane-2,4-dione and ammonia to give the pyridine derivative (Scheme 13b). Detection is achieved by monitoring the absorption of the substituted pyridine.40 The method is ideally suited for the determination of alditols separated in the anion-exchange mode as borate complexes. Fluorimetric monitoring gives a sensitivity of 0.5 nmol of alditol. As the initial oxidation step with periodate is carried out at high pH, aldoses or ketoses will also

release formaldehyde, but only 1 mol per mole instead of 2 mol per mole for alditols. In one of the earliest reports on the use of fluorogenic reagents being used in the detection of reducing sugars, solutions of carbohydrates heated with 1,2-diaminoethane (ethylene-diamine) produced a strong fluorescence at 470 nm, with an excitation maximum at 390 nm. This has been developed as a selective fluorimetric method for the determination of mono- and oligosaccharides and uronic acids. Increased sensitivity, down to 1 pmol of monosaccharide, could be achieved when the reaction products were electrochemically oxidized on a glassy carbon electrode. 2-Cyanoacetamide has proved to be a very versatile fluorogenic molecule, because aldoses heated in weakly alkaline solutions with this reagent produce an intense fluorescence at 380 nm. The reaction products also absorb strongly at 280 nm, and can also be detected by electrolysis at a glass carbon electrode, thus allowing any one of three detection methods to be used. The reaction conditions for the photometric and fluorimetric detection differ and have been optimized separately. For separations on HPLC columns with acetonitrile as eluant, only UV monitoring is possible with this derivative.

Reducing sugars when heated with strong alkali and aromatic acid hydrazides produce yellow colors, which have been used as the basis of detection systems. The reagent Purpald, which was originally developed as a spray for the detection of reducing sugars on TLC plates, can be used for the postcolumn detection of aldoses. The reaction is carried out in the presence of sodium hydroxide and hydrogen peroxide to produce a tetrazine–triazole fused ring condensate (Scheme 14).

![Scheme 14 Reaction of Purpald with an aldose.](image)

Amino sugars are present in the total acid hydrolysates of most glycoproteins and proteoglycans. These sugars exist in macromolecules such as N-acetyl hexosamines, but the N-acetyl group is hydrolyzed under the acid conditions. The amino sugars can be chromatographed and detected in addition to the amino acids, on conventional amino acid analyzers with ninhydrin reagents. The same reagent may be used for the determination of monosaccharides which have been converted to glycamines (Scheme 12) prior to ion-exchange chromatography.

### 4.4 Electrophoresis

#### 4.4.1 Capillary Electrophoresis

CE, which had earlier been shown to give fast, automated and highly efficient separations of peptides, proteins and nucleic acids, has been developed into a technique for the analysis of mono- and oligosaccharides and glycoproteins. The CE method now provides a powerful alternative to HPLC for the detection of carbohydrates. Its popularity is reflected in the number of recent review articles dealing with current methods and general principles. Carbohydrates are separated in CE, under the influence of an applied electric field (5–30 kV), by migrating in capillary columns (0.5–1.5 m long, 50–100 μm internal diameter), which span two buffer reservoirs and which are filled with buffer solutions. Total capillary volumes can be 10 μL, and injection volumes can be in the range of a few nanoliters. Factors influencing the mobility of carbohydrates include the applied voltage, the charge on the sugar molecule (positive, negative, or neutral), the pH and ionic strength of the buffer, the presence of buffer additives (surfactants, ion-pairing agents), and the operating temperature inside the capillary, as well as its length and diameter. Capillary columns are generally constructed from fused silica and carry negative charges on the inner surface due to the presence of silanol groups, which are ionized above pH 3.0. Two forces – electro-osmotic flow and electrophoresis – govern the mobility of the carbohydrates. The electro-osmotic flow drives all species, irrespective of charge, from the injector, through the capillary, to the detector. This flow results from the cations in the buffer being attracted to the negatively charged silanol groups on the surface of the capillary. Under an applied high voltage, the cations migrate from the anode to the cathode, resulting in a bulk flow of electrolytes (electro-osmotic flow). The electrophoretic force, which also influences the separation of the species, is considered to be weaker.

The separation of both neutral and charged sugars may be achieved by either of two modes. The most common mode uses normal polarity (positive polarity) in which a neutral or basic buffer is used, sample application is at the anode, and detection is at the cathode. Therefore sugars bearing a positive charge will elute first, followed by neutral sugars. Negatively charged sugars are retarded because of electro-osmotic flow. In the second system, reversed polarity (negative polarity) acidic buffers are used. Electro-osmotic flow is reduced or eliminated, because of loss of charge on the silanol groups. Electrophoresis is then the dominant force, and only the anionic species migrate towards the anode. Electro-osmotic flow may also be eliminated by coating the capillaries with poly(vinyl alcohol). As only a relatively small number of monosaccharides (amino sugars, uronic
Carbohydrates are readily detectable after precolumn derivatization, giving products suitable for UV and fluorescence detection. This is the preferred approach for the electrophoresis and detection of monosaccharides. General methods to achieve derivatization include reductive amination, condensation of carboxylic groups on saccharides with amines, or condensation with PMP. The chemistries involved are shown in Schemes 10, 15 and 16.

The use of 2-AP as a label for monosaccharides, after reductive amination, was originally developed for the precolumn labeling of monosaccharides for HPLC (Table 4). From these N-2-pyridyl-glycamines derivatives, monosaccharides give a rapid separation in borate buffer at pH 10.5. 2-AP reacts satisfactorily with aldoses, alduronic acids, and N-acetamido-hexoses, but not with ketoses. An alternative number of carbohydrate labels based on aminobenzene, including 4-aminobenzoic acid, ethyl 4-aminobenzoate, and 4-aminobenzonitrile give derivatives with ketoses. On-column detection of 6-aminoquinoline derivatives at 245 nm, using borate based electrolytes, has been used to give very sensitive detection of monosaccharides in wood-derived hemicelluloses. The minimal detectable amount is reported to be a few femtomol with concentration limits of detection of the order of 10^{-6} M.

Other commonly used derivatives for precolumn labeling of monosaccharides, using reductive amination chemistry, include ANTS and 8-aminopyrene-1,3,6-trisulfonic acid (APTS). Two major advantages shown by these derivatives are that, as they exhibit very high extinction coefficients in the UV range, they can be detected photometrically at very low levels by LIF, and that the negative

charges on the sulfonic acid groups are so strong that they are dissociated even in acidic media. In the analysis of the monosaccharide composition of glycoproteins, APTS has been used to derivatize the monosaccharide components. Neuraminic acid was separately derivatized with 9-aminoacridone.\(^{214}\)

Isoindole derivatives of monosaccharides that give very sensitive labels are obtained from a two-step derivatization process. In the first step, sugars are converted to the corresponding glycamines by reductive amination (Scheme 17) prior to condensation with CBQCA in the presence of the cyanide ion.\(^{215}\) The highly fluorescent isoindole derivatives of monosaccharides can be determined at attomole (\(10^{-18}\)) levels by LIF. The advantages and disadvantages of fluorescence and LIF have been examined in detail.\(^{216}\)

In another two-step derivatization method for monosaccharides, neutral sugars are converted to glycamines by reductive amination (Scheme 12). Amino sugars are reduced to the corresponding 2-amino-2-deoxyalditols. These aminated sugars are then labeled with TRSE (Scheme 18). Difficulties have been reported with the stability of these derivatives, but, nevertheless, successful separations of hexoses derived from mammalian glycoproteins have been achieved with a concentration detection limit of \(5 \times 10^{-11}\) M.\(^{217}\)

The formation of amide bonds from the condensation of carboxyl groups and amino groups in the presence of carbodiimide is a well-documented chemical process. Amide bond formation between alduronic acid residues and amines, such as 4-aminobenzene sulfonic acid (sulfanilic acid), and 7-aminonaphthalene-1,3-disulfonic acid (ANDSA) have been used to produce labeled carbohydrates (Scheme 15). The labeled products are strongly anionic at low or high pH levels. UV detection at 247 nm results in mass detection limits of 30 fmol for sulfanilic acid and 15 fmol for the ANDSA derivatives.\(^{208}\) Under mildly basic conditions, PMP reacts with aldoses to form bis-PMP derivatives (Scheme 16). These derivatives, originally developed for HPLC, are used in capillary electrophoretic separations of mono- and oligosaccharides.\(^{209}\)

4.4.2 Fluorophore-assisted Carbohydrate Electrophoresis

The FACE method is based, first, on the attachment of fluorescent tags to the reducing end of carbohydrates using standard reductive amination techniques prior to the separation of the derivatives on polyacrylamide (PA) gel slabs.\(^{218 - 220}\) This technique has been used mainly for routine oligosaccharide profiling and sequencing of a variety of carbohydrates, as well as for monosaccharide analysis. The fluorophore most often used is ANTS.\(^{221}\) Neutral and acidic monosaccharide derivatives exhibit net negative charges, imparted from the three sulfonic acid groups, and can be separated by electrophoresis and detected by their fluorescence. The alternative fluorophore, AMAC, which confers no charge on monosaccharide derivatives, is also used. In this case, borate ions, which complex with vicinal hydroxyl groups of monosaccharides, impart a negative

---

**Scheme 17** Conversion of aldoses to isoindole derivatives.

**Scheme 18** Conversion of glycamines into TRSE derivatives.
charge for electrophoresis. These derivatives are analyzed by polyacrylamide gel electrophoresis (PAGE). High-resolution separations are achieved by virtue of the electrophoretic buffer systems used. These are so-called stacking systems that are also called discontinuous, moving boundary, multizone, or multiphase. The PA gel inhibits convection. The resultant electrofluorograms are viewed on a graphics display unit after imaging with a suitable electronics camera.

Some ANTS-fluorophore derivatives of monosaccharides, oligosaccharides and low-molecular-weight polysaccharides have been separated by PAGE. For monosaccharides, high-resolution separations of some pairs of isomers, anomers and epimers have been achieved.

The isolation and analysis of proteoglycans (PGs) and the acidic polysaccharide glycosaminoglycan (GAG) chains attached to them is an area of increasing importance. PGs are a structurally diverse group of complex macromolecules comprising a core protein, varying in size from 11 to 400 kDa, to which are attached one or more GAG chains of the same or a different type. These chains carry a negative charge derived mainly from sulfate groups and are composed of a repeating disaccharide, a hexosamine and either a hexuronic acid or, in keratan sulfate (KS), galactose.

1 INTRODUCTION

The isolation and analysis of PGs and the acidic polysaccharide GAG chain attached to them is an area of increasing importance. PGs are a structurally diverse group of complex macromolecules comprising a core protein, varying in size from 11 kDa to 400 kDa, to which are attached one or more GAG chains of the same or a different type (Table 1). These chains carry a negative charge derived mainly from sulfate groups and are composed of a repeating disaccharide, a hexosamine and either a hexuronic acid or, in KS, galactose.

2 PROTEOGLYCANS

PGs are found on mammalian cell surfaces and in extracellular matrixes, in plants, and in invertebrates (Table 1). Several large PGs share features and properties with the prototypical member of the class, the large aggregating PG aggregcan (Table 1). Aggrecan monomers comprise a protein core of ca. 250 kDa to which are attached ca. 100 CS and ca. 50 KS chains. Up to 100 of these monomers form large aggregates of up to 5 x 10^6 kDa through interaction with hyaluronate (HA). Small leucine-rich PGs have a protein core comprising leucine-rich tandem repeats of ca. 24 amino acids.

CS, chondroitin sulfate; DS, dermatan sulfate; HS, heparan sulfate; TGF-β, transforming growth factor beta.

repeated up to 12 times, a motif which may be involved in binding to other macromolecules. (6)

Fibromodulin is glycosylated by four short N-linked KS chains (7–10) attached within, or close to, the leucine-rich repeat region. This is in contrast to both decorin and biglycan in which the CS/DS chains are located close to the N-terminus. There is evidence that fibromodulin, along with decorin, has a role in the maintenance of the collagen fibrils which make up the extracellular matrix of cartilage. The core protein of fibromodulin binds to collagen monomers (11,12) and the KS chains apparently control fibril diameter and interfibrillar spacing. (13)

2.1 Is my Protein Glycosylated?

If it is suspected that an isolated macromolecule is a PG, the presence of glycosylation should be confirmed; later, the nature of the carbohydrate may be investigated. This is most easily done using a commercial carbohydrate detection kit, which relies upon the oxidation of adjacent hydroxyl groups in carbohydrates to aldehydes. The aldehydes react with either digoxigenin (Roche Molecular Biochemicals, http://193.197.95.199 Glycan Detection Kit) or biotin hydrazide (Glyko, http://www.glyko.com) and are detected using peroxidase or alkaline phosphatase conjugated to an antibody or to streptavidin, respectively.

2.2 Inhibition of Glycosylation

An unglycosylated PG core protein may be expressed in culture if a glycosylation inhibitor is present. Inhibitors include deoxynojirimycin and swainsonine, which block the processing of high-mannose oligosaccharides to complex oligosaccharides; however, swainsonine does not affect hybrid chains. In contrast, tunicamycin inhibits the formation of dolichol pyrophosphate N-acetylglucosamine. All of these inhibitors will inhibit N- but not O-linked chain synthesis.

2.3 Metabolic Labeling During Synthesis

A radiolabel may be introduced by addition of 35S- or 3H-containing substrates to the growth media during culture. Radiolabeled [35S]sulfate is incorporated into GAGs to examine sulfation, [3H]glucosamine will label most GAGs, [3H]glucose is converted to many sugar precursors and becomes incorporated into most carbohydrates, while [3H]mannose will label only N-linked chains. If [3H]leucine is used then the protein core, along with all other proteins, will be labeled. Radiolabeling can provide a measure of synthesis and sulfation under modified growth conditions, as only newly synthesized molecules are labeled, while pulse chase experiments can provide information on turnover.

2.4 Extraction

A tissue or cell layer can contain many different PGs and their structure and extractability may differ widely, so no single protocol is appropriate for the extraction, isolation and analysis of all PGs. In a tissue such as cartilage they may be trapped by the collagen meshwork
or bound by noncovalent interactions to other molecules, while brain PGs are very readily extracted. Cell surface PGs may be attached via a hydrophobic domain or phosphatidylinositol anchor while other PGs are found intracellularly.

Unless an extraction protocol has already been established, both 4 M guanidine hydrochloride (GuHCl) and 4% 3-(3-cholamidopropyl)dimethylammonio)-1-propanesulfonate (CHAPS) should be included in an extraction buffer. The zwitterionic detergent CHAPS is easier to remove subsequently than the micelle-forming Triton™ X-100, and its inclusion when extracting cells reduces artificial hydrophobic interactions induced by GuHCl. (14)

Extraction of cartilage PGs (15) is performed for 24 h at 4 °C into 7–10 mL g⁻¹ of tissue with 4 M GuHCl, 50 mM sodium acetate (pH 6.8), 100 mM 6-aminohepxanoic acid, 20 mM benzamidine hydrochloride, 0.5 mM phenylmethylsulfonyl fluoride, 10 mM ethylenediamine tetraacetic acid (EDTA) and 5 mM N-ethylmaleimide, to prevent degradation. Extraction efficiency is increased if the tissue pieces are small; ideally 20-µm cryostat sections or chopped or powdered tissue should be used. Powdered tissue is obtained by pulverizing the tissue after freezing in liquid nitrogen, although there is some evidence of damage to PGs using this method. (16) Connective tissues contain insoluble collagen and inextractable PGs and GAGs which are only accessed by digestion of the collagen network or release of the GAGs (see section 3.1).

### 2.5 Isolation

Methods used in the separation of PGs from each other, and from nonPGs, often focus on the negative charge generated by the attached GAGs. However, other properties can also be utilized; PGs have larger hydrodynamic volumes and buoyant densities than the size of their protein cores would suggest, and cell surface PGs often have a hydrophobic transmembrane region.

#### 2.5.1 Centrifugal Techniques

The high buoyant density of PGs allows the almost pure single-step isolation of large PGs in a self-forming CsCl density gradient. Smaller PGs also benefit, becoming separated from larger PGs and smaller proteins. If >0.5 M GuHCl is present the gradient is dissociative and may thus be used to isolate PGs from other extracted macromolecules with which they interact; at lower GuHCl concentrations the gradient is associative. CsCl is added to an extract to achieve a density of 1.6 g mL⁻¹ using

\[
X = V(1.347\rho - 0.038M - 1.347),
\]

where \( X \) is weight of CsCl in grams, \( V \) is final volume, \( M \) is molarity of GuHCl, and \( \rho \) = density. The density should be confirmed by weighing a 1-mL sample before ultracentrifugation at 88,500g for 48 h at 12 °C. If cell surface PGs are being isolated, or the PG is believed to be hydrophobic, 0.5% CHAPS should also be included. (15)

Following centrifugation the gradient can be fractionated by sucking the solution out from the bottom of the tube with a peristaltic pump attached to a stiff, hollow tube, or by piercing the bottom of the tube and allowing the gradient to drip out. The fractions should be assayed for density and for GAGs or PGs of interest, then pooled appropriately. Large PGs such as aggrecan are found at the bottom (>ca. 1.5 g mL⁻¹, A1), while small PGs such as fibromodulin, decorin and biglycan are present towards the top (<ca. 1.45 g mL⁻¹, A3/A4). (17)

#### 2.5.2 Chromatographic Analysis

Before their first use for chromatography of PGs or GAGs it is necessary to condition all column media with Cs and BSA (bovine serum albumin) (both ca. 1 mg mL⁻¹) to prevent nonspecific binding of the samples.

#### 2.5.2.1 Ion-exchange Chromatography

The negative charge of the GAGs attached to PGs brings about their binding to anion-exchange matrices and their separation from both uncharged macromolecules and from each other in an appropriate elution gradient. The method is not sensitive to sample volume or to chaotropic agents, and so is often used as the first chromatographic step during purification. Nonspecific adsorption of nonPGs and less than 100% recovery of bound PGs may be minimized by careful attention to the capacity of the matrix and column size, or the amount of resin when used in batch mode, together with a low, nonzero, salt concentration in the starting buffer.

For example fibromodulin is isolated in an almost pure form by ion-exchange chromatography (IEC) following CsCl density gradient centrifugation, where it bands at A3/A4. It is eluted from a Mono-Q® HR 10/10 column with a linear gradient of 0.15–1 M NaCl in 6 M urea/50 mM TRIS (tris(hydroxymethyl)aminomethane)-HCl, pH 7.3, and is found in the fractions between 0.4 and 0.8 M NaCl. The related small PGs decorin and biglycan elute at higher salt concentrations (Figure 1). The eluent is monitored online at 280 nm and fractions are assayed for GAG and PGs. Nucleic acids, however, which are common in cell extracts, may bind to anion-exchange resins, and the 1,9-dimethylmethylene blue (DMB) assay (see section 3.3.5) which will respond to GAGs but not nucleic acids should be used to reliably estimate GAG abundance.
2.5.2.2 Size-exclusion Chromatography

Size-exclusion chromatography (SEC) is widely used for the isolation and analysis of molecules of all sizes. Because of the large apparent hydrodynamic volume of PGs, and GAGs, quoted ranges for globular proteins may not be a good measure for the appropriateness of a column. Chromatography will usually be performed using a salt-containing eluent to inhibit interactions with the resin. One exception is Bio-Gel® P2, which may be used at 50°C in distilled water (dH2O) for desalting. A volatile salt such as ammonium acetate may obviate the need to desalt before subsequent analysis, but during lyophilization significant drops in the pH can occur which have been found to cause the loss of labile groups such as N-acetylgalactosamine (NeuAc). For large PGs, such as aggregan, CL-2B resin allows isolation of the aggregated PG under associative conditions and isolation of the monomers under dissociative conditions. Tryptic digest products of aggregan can be isolated using a CL-6B column while smaller PGs may be isolated using CL-6B, Superose 6, S-300 or HW-55s. The final choice of medium will depend upon the structure of the PG under investigation and the nature of the material it is being separated from.

2.5.2.3 Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography (HIC) relies upon the hydrophobicity of a molecule and separation is performed in a gradient of decreasing salt or increasing chaotropic agent or CHAPS. In common with IEC, it is not sensitive to loading volume but is not able to support the high sample loading of IEC. Factors including temperature and pH affect elution, with increasing temperature retarding elution.

Decorin and biglycan, which co-elute from a Mono-Q® column (Figure 1), are separated on a 300-mL Octyl-Sepharose® HIC® column. The PG mixture (40 mg) should be applied in 4 M or 2 M GuHCl and eluted with a gradient of 0–1% CHAPS or 2–6 M GuHCl respectively.

2.5.2.4 Reversed-phase Chromatography

Reversed-phase chromatography (RPC) is not widely used in the isolation of PGs because of its low capacity and the fact that the nonpolar stationary phase may denature a PG. However, the high resolution attainable makes it appropriate for confirming purity as elution is dictated almost exclusively by the peptide. It is also used in the separation of PG fragments generated by tryptic degradation.
digestion for the isolation of a GAG attached to a specific glycosylation site.\(^{(10)}\)

### 2.5.3 Immunopurification

If an antibody to the PG or the attached GAG chains is available it may be conjugated to a medium such as Dyna-Beads\(^{\text{TM}}\) or to a column support matrix that allows isolation by immunopurification.

### 2.6 Analysis of Intact Proteoglycan

#### 2.6.1 Electrophoresis of Proteoglycan or Protein Core

The resolution of PGs by SDS/PAGE (sodium dodecyl sulfate/polyacrylamide gel electrophoresis) is often poor because of the polydispersity of chain sulfation and size. Small PGs have been successfully separated using electrophoresis on 8–20% gradient gels and although large PGs will not enter a conventional gel they may be electrophoretically separated on 1.2% polyacrylamide–0.6% agarose.\(^{(17,19)}\) For this procedure an acrylamide plug is made by mixing 10 mL of 30% acrylamide (comprising 29.1% acrylamide–0.9% bisacrylamide) with 18.47 mL of distilled water, 30 mL of \(N,N,N',N'\text{-tetramethylethlenediamine}\) and 1.5 mL of fresh 3% ammonium persulfate. A ca. 3-cm plug is poured and then overlaid with \(\text{dH}_2\text{O}\) saturated butanol. Then 0.24 g of agarose is added to 22.5 mL of solution A (40 mM TRIS-acetate–1 mM sodium sulfate, pH 6.8), and brought to the boil. Acrylamide (0.456 g) and 0.024 g of bisacrylamide are dissolved in 9.7 mL of solution A, then 4.8 mL of fresh 6.4% \(\beta\)-dimethylamino-propionitrile is added and the mixture is warmed. The plug is blotted dry and heated to 60 °C. When the boiled agarose solution has cooled to 50 °C, 3 mL of 3% ammonium persulfate is added to the acrylamide solution, and mixed and added to the agarose. The mixture is poured onto the plug, and a well former is inserted and overlaid with \(\text{dH}_2\text{O}\) saturated butanol.

Aggrecan monomers (5 \(\mu\)L at 1 mg mL\(^{-1}\)) in 25% solution A containing 20% sucrose and 0.001% bromophenol blue are then applied to each well. Electrophoresis is carried out in 25% solution A at 60 V until the dye enters the gel, then at 120 V; the PGs should not approach the supporting plug too closely. Following electrophoresis the gel is stained in 200 mg toluidine blue–100 mL 0.1 M acetic acid and destained in 3% acetic acid. Radiolabeled PGs are visualized by fluorography of a fixed gel (15 mM sodium acetate in ethanol containing 0.4% PPO (2,5-diphenyloxazole)). The \(\text{dH}_2\text{O}\) washed and dried gel is sealed in a light-tight box in contact with pre-flashed X-ray film at −70 °C. Exposure time depends upon activity, but as a general guide 1000 dpm (disintegrations per minute) \(^{35}\)S requires ca. 48 h of exposure.

#### 2.6.2 Enzyme-linked Immunosorbent Assay

ELISA is a well-established technique for the detection and quantification of structures for which an antibody is available. There are two methods, namely direct and inhibition. The former is appropriate for rapid determinations of the presence of a PG, and the latter more complex method is used for quantitative analyses. In a direct ELISA a sample is coated onto the well of a microtiter plate in 20 mM sodium carbonate at pH 9.6, and after washing in phosphate-buffered saline (PBS) with 0.5% Tween 20 to remove unbound material (performed after each step) an antibody to the antigen of interest is added to each well. This is followed after 1 h by an enzyme-conjugated second antibody which binds to the first. A substrate for the enzyme which generates a colored product is added, and after a fixed time the abundance of this product is estimated by measuring its absorbance, which is proportional to the concentration of the original antigen of interest. In an inhibition ELISA the sample and primary antibody are pre-incubated and then transferred to a microtiter plate, the wells of which are coated in a standard containing an example of the antigen being examined. Excess primary antibody binds to this coated material and may be estimated as described previously.

#### 2.6.3 Nuclear Magnetic Resonance and Mass Spectroscopy

Nuclear magnetic resonance (NMR) is a powerful, nondestructive technique, allowing the analysis of an intact PG and its recovery for further analysis. Because a PG is large, signals deriving from the amino acid backbone will be complex, but if aromatic residues are present they will have signals in the otherwise clear area at ca. 7–8 ppm. It can be difficult to get GAG-related information from spectra acquired with an intact PG, although there are some key regions from which information can be derived that are generally free of protein signals. Samples need not be completely pure, although it is typically necessary to have ca. 0.5–1 mg of sample. However, complete \(^1\)H characterization of an octasaccharide has been reported where less than 125 \(\mu\)g of sample was available.\(^{(20)}\)

Mass spectroscopy (MS) techniques allow the accurate estimation of the mass of an intact PG as the heterogeneity of peaks reflects the heterogeneity of post-translational processing, including glycosylation. Clearly the estimation of mass before and after removal of any GAG chains will allow a determination of the mass of GAGs removed, providing what is potentially a very powerful method for the determination of the nature and size of a GAG along with its enzymatic susceptibility.
2.7 Removal of Glycosaminoglycans to Yield an Intact Protein Core

Peptide-N4-(acetyl-glucosaminyl)-asparagine amidase (EC 3.5.1.52, PNGase F) will release many N-linked KS chains by breaking the GlcNAc-Asn bond and completely removing the GAG chain leaving both it and the protein core intact, except for the deamination of Asn to aspartic acid. It acts upon Asn-linked high mannose, hybrid and complex oligosaccharides, but will not act upon chains which contain fucose (1,3)-linked to the terminal GlcNAc, although α(1,6)-linked fucose has no effect; the Asn must have at least one amino acid residue on both sides (Figure 2).

The PG should be heat denatured with a minimum volume of 1% SDS (sodium dodecyl sulfate) and 1 M β-mercaptoethanol by heating at 100 °C for 5 min. Following cooling Triton™ X-100 is added at 5× excess relative to SDS. PNGase F is then added at 1 U per 20 mg of PG and allowed to digest for 12 h at 37 °C. This can be extended to 24 h if the PG is not denatured or the effect of SDS is not reduced by Triton™. The enzyme is extremely robust and will remain active in the digestion buffer for over 24 h.

There are other endoglycosidases that act upon N-linked chains, although none release the intact chain. Endoglycosidase A (PNGase A, EC 3.5.1.52) cleaves chains with fucose α(1,3)-linked to the terminal GlcNAc; chains upon which PNGase F will not act. However cleavage occurs between the two linkage region GlcNAc residues leaving a single GlcNAc attached to the protein core. There are several endoglycosidase Fs (EC 3.2.1.96) that have significantly different substrate specificities, so it is crucial to confirm the specificity of the enzyme purchased. Each endoglycosidase F cleaves between the two GlcNAc residues of the linkage region: F1 cleaves hybrid and oligomannose (but not complex) oligosaccharides; F2 cleaves high mannose and biantennary complex oligosaccharides, showing a significant preference for the complex type, and no activity towards hybrid type or tri- and tetraantennary oligosaccharides; F3 cleaves only bi- and triantennary complex type oligosaccharides, showing no activity towards hybrid or high mannose type.

No single enzyme will remove all O-linked GAGs, and chains must be depolymerized to leave the linkage disaccharide Galβ(1-3)GalNAc, which may be removed using endo-O-glycosidase (O-glycopeptide endo-D-galactosyl-N-acetyl-a-galactosaminohydrolase, EC 3.2.1.97) only following the removal of the rest of the chain (Figure 2).

CS/DS chains may be depolymerized by chondroitin ABC lyase (EC 4.2.2.4) (Figure 3), and the terminal

---

**Figure 2** Structural models of KS and specificity of chemical and enzymatic methods for depolymerization. Structural models for corneal and skeletal KS are shown; note the absence of α(2-6)-linked NeuAc and fucose in both O- and N-linked KSs from nonarticular cartilage. The specificity of methods of depolymerizing KS are also shown. For the repeat region 1 = endo-β-galactosidase, 2 = keratanase, 3 = keratanase II and 4 = hydrazinolysis/nitrous acid. ✓ = can cleave, × = cannot cleave, ? = unknown.
**Figure 3** Specificity of CS degrading procedures. The specificity of enzymatic and chemical methods of depolymerizing CS are shown. A and B refer to enzyme action on intact chains while C and D are isolated tetrasaccharides; 1 = chondroitin ABC endo/exo lyase; 2 = chondroitin; a = ACI; b = ACII; c = ACIII (if (a), (b) and (c) are not shown separately all can cleave) and 3 = chondroitin C lyase. Chondroitin B lyase acts solely upon DS. ✓ = can cleave, × = cannot cleave, ? = unknown.
that the enzyme generates can be removed using 35 mM mercuric acetate, pH 5, at ambient temperature for 30 min, excess Hg being removed by cation-exchange chromatography. The Gal residues may then be cleaved by β-galactosidase (EC 3.2.1.23), which acts only upon a terminal residue. The remaining xylose requires a xylolysidase for its cleavage. Such enzymes have been isolated and used to remove the intact chain, but are not commercially available at present; their widespread availability will represent a significant advance in the isolation of O-linked GAG chains.

Heparin/HS may be depolymerized and the remaining linkage region removed as described for CS/DS, but there is no single enzyme that will depolymerize all chains leaving the linkage region (see section 7.2).

Enzymatic methods are specific but they may not always be appropriate, e.g. if there is a spectrum of GAGs of known or unknown type, or if their structure is such that enzymatic deglycosylation fails. In contrast chemical deglycosylation methods have a broad specificity and may be used to deglycosylate a PG with GAG chains of an unknown type. Techniques used include anhydrous HF at 23°C for 3 h, which cleaves neutral and acidic sugars along with O-glycosidic links but not N-glycosidic links, 70% HF in pyridine with 10% anisole at ambient temperature for 8 h, and Smith degradation and methanolysis for 17 h at 80°C. Note however that there are reports of variable removal of carbohydrates and solubility problems following deglycosylation by HF methods. Gerken et al., (25) in a modification of the method of Edge et al., (20) used trifluoromethanesulfonic acid (TFMS). Anisole and TFMS are mixed 1 : 2 in a glass tube, cooled in a dry ice–ethanol slurry and 1 mL was added to 5–10 mg of dry sample. Nitrogen was bubbled through the solution for 30 s followed by stirring at 0°C for 6 h after which 1 volume of cold anhydrous diethyl ether was added and the mixture slowly added to 12.5 mL of a frozen slush of 60% pyridine. The mixture was allowed to warm to ambient temperature and extracted with ether, the aqueous phase being recovered. Subsequent periodate oxidation followed by an alkaline dialysis was required to remove the linkage residue remaining attached to the core protein. This method has been used to deglycosylate O- and N-linked KS, no studies have examined its action on CS/DS and heparin/HS, although it would be expected to deglycosylate these GAGs.

The removal of a GAG chain may modify the structure or properties of the intact protein core by exposure of previously masked regions, or through disruption of intramolecular interactions.

### 2.8 Amino Acid Analysis

Amino acid analysis can be very important in the identification of a PG. A pure sample, ca. 20–100 µg, should be subjected to vapor phase acid hydrolysis with

**Figure 4** Amino acid analysis of fibromodulin. An aliquot (1 µL) of a PITC derivatized hydrolysate was applied to a Spherisorb® ODS (3 µm 150 × 4.6 mm) column and the amino acids were eluted at 1.5 mL min⁻¹ in 0–100% buffer B (50% acetonitrile–50% 24 mM sodium phosphate, pH 6.4). Buffer A is 12 mM sodium phosphate, pH 6.4.
6 M HCl at 105 °C for 24 h, followed by lyophilization and a redrying step in 40% ethanol–20% triethylamine–40% water. Under basic conditions amino groups are coupled to phenylisothiocyanate (PITC) in 70% ethanol–19% water–10% triethylamine–1% PITC at 25 °C for 20 min. Free PITC will poison the column (Spherisorb® ODS 2–3 µm 150 × 4.6 mm) and must be removed by lyophilization prior to chromatography. Labeled amino acids are unstable at ambient temperature and should be stored at −80 °C. Aliquots are resuspended in a minimum volume of buffer A (12 mM sodium phosphate, pH 6.4) and chromatographed at 1.5 mL min⁻¹ with a gradient of 0–100% buffer B (50% acetonitrile–50% 24 mM sodium phosphate, pH 6.4) with detection by absorbance at 245 nm (Figure 4).

A control protein should be examined to estimate losses, and the column calibrated with commercial amino acids labeled with PITC. When the composition has been determined, searching the Swiss-Prot database (http://www.expasy.ch/tools/aacomp/) for entries with the appropriate composition may yield the identity of an unknown. If the sequence is available there are tools for the analysis of this data (http://www.expasy.ch/tools/). The NetOGlyc site (http://www.cbs.dtu.dk/services/NetOGlyc/) predicts O-glycosylation sites in mammalian PGs where the sequence is known.

2.9 Where are the Chains Attached?
The primary amino acid requirements for glycosylation are well established, but not all potential sites are necessarily glycosylated. Experimentally, a blank cycle at a potential glycosylation site during amino acid sequencing points to the presence of a glycosubstitution. An elegant approach was taken by Plaas et al. who used trypsin to digest a PG and isolated the peptido-KS chains by IEC. Then they used RPC to separate these into pools with the same amino acid sequence. The GAG chains of each pool were characterized and the peptide sequenced, identifying its position in the parent PG and thus revealing the nature of the glycosylation at a specific site.

3 ACIDIC POLYSACCHARIDES
In mammalian tissues there are four GAGs: HA, KS, CS/DS and HS/heparin (Figure 5) which, with the exception of HA, are synthesized attached to PGs and comprise a chain cap, a linkage region which connects the chain to the protein core, and an intervening repeat region. The repeat regions consist of a repeating disaccharide comprising a hexosamine and either a hexuronic acid or, in KS, galactose (Figure 5). Each residue, apart from those of HA which exist as an invariant linear sequence without sulfation or other modifications, may be sulfated, in some cases by more than one sulfate group, rendering GAGs highly negatively charged.

The detailed microstructure of GAGs is crucial to their function, e.g. 4-sulfated GalNAc in CS has a role in the adherence of the malaria parasite to human placenta; iduronic acid (IdoA) is required for binding DS to the growth promoter spermine and N- and 2-O-sulfate groups on the HS of syndecan-1 are important in collagen binding. Other important GAG structures include that of the antithrombin III binding site in heparin, the heparin cofactor II binding site in DS and the bFGF binding sequences in HS.

3.1 Release of Intact Carbohydrates from the Protein Core
Enzymatic procedures for the removal of N-linked GAGs yield the intact chain (see section 2.7), but as discussed previously no such method exists for O-linked chains, and alternative approaches are required.

3.1.1 β-Elimination
Chains that are O-linked are alkali labile and incubation in 0.1 M NaOH at 45 °C or 0.05 M LiOH at 4 °C for 24 h will release them. The former method
requires 1 M NaBH₄ to reduce the released chains and prevent degradation due to the high pH, while the latter allows the isolation of intact chains terminated with a reducing sugar. This residue has been used to fluorescently label the CS linkage region for high pH anion-exchange chromatography (HPAEC) analysis and sequencing. Although not readily alkali-labile, N-linked KS chains may be liberated by strongly alkaline conditions such as 1 M NaOH–1 M NaBH₄ at 100 °C for 4–6 h.

### 3.1.2 Hydrazinolysis

Chains with either N- or O-linkages may be released unredirected by hydrazinolysis. Lyophilized samples (5–10 mg mL⁻¹) are resuspended in anhydrous hydrazine and heated to 60 °C for 5 h to release O-linked chains and to 95 °C for 5 h to release N- and O-linked chains. Excess hydrazine, made safe by the addition of one volume of dH₂O, is removed by evaporation under vacuum at 25 °C. Primary amino groups are re-N-acetylated by an excess of 0.5 M acetic anhydride in saturated NaHCO₃ at 4 °C for 20 min and then at ambient temperature for 30 min. The procedure may also be performed by automated hydrazinolysis, which is reported to require a minimum of ca. 50 µg of sample for efficient release and recovery.

### 3.1.3 Digestion/Destruction of Protein

If the amino acid on the protein core to which the GAG chain is attached is to be retained, or if complete release is not essential, the protein core may be extensively digested by a broad specificity protease such as papain. It is used at a level of 1 U per 100 mg of tissue in 0.1 M sodium acetate at pH 6.8 with 2.4 mM EDTA and 10 mM cysteine HCl, added just prior to digestion, at 60 °C overnight. The mixture is boiled for 30 min or iodoacetamide is added to 10 mM to inactivate. The elevated temperature at which papain digestion is performed gives it a significant advantage over the use of other proteases as unwanted enzymatic activity will be prevented. The remaining peptide may then be used to conjugate biotin, or any other label or probe, via the amino terminus.

### 3.2 Isolation of Glycosaminoglycans from Other Glycosaminoglycan and Nonglycosaminoglycan Contaminants

GAGs which have been released from their protein core need to be separated from peptides and may need to be fractionated if more than one GAG is present. The choice of method depends upon the amount of GAG expected, what it is being separated from, and the required purity.

#### 3.2.1 Precipitation

The GAGs have different solubility in organic solvents, and are precipitated by the careful addition of ethanol while stirring to the following total number of volumes: heparin 0.1–0.4, DS 0.5–0.8, CS 2. KS 3. After 15 h at 4 °C the GAGs appear as a white precipitate or a sticky mass which is easily recovered. Higher purity will be achieved by precipitating all GAGs, resuspending them in an appropriate volume of 0.1 M sodium acetate, and performing another series of ethanol precipitations. Volpi used the following volumes of propanol for precipitation: heparin 0.3–0.4 volumes, DS 0.5–0.6 volumes and CS > 0.8 volumes.

Cetyl pyridinium chloride (CPC) can also precipitate GAGs. Following papain digestion, 1% CPC is added and the mixture is centrifuged for 1 h, then the pellet is washed with NaOAc saturated ethanol.

#### 3.2.2 Chromatographic Separation Methods

GAGs may be separated from nonGAG material by IEC, essentially as discussed for intact PGs. KS chains have been successfully isolated from nonGAGs and from contaminating CS using Mono-Q® or Q-Sepharose® IEC in a gradient of 2–500 mM LiClO₄–10 mM piperazine. Many IEC methods suffer from less than 100% recovery and use of a column with appropriate dimensions is important. Other strategies appropriate for the isolation of labeled GAGs involve the use of unlabeled carrier. Alternatively, intact GAG chains can be separated from smaller oligosaccharides by SEC.

#### 3.2.3 Dialysis

Dialysis and centrifugal partition utilize a membrane through which small molecules such as salt and depolymerized oligosaccharides will pass, but larger molecules will not. Dialysis is appropriate if the GAG is abundant and in a large volume. However, if the amount of GAG and the volume it is in are small, then centrifugal partition will allow its separation from salt and smaller oligosaccharides, and permit it to be recovered in a small volume. The use of a high-quality dialysis membrane with a closely defined pore size is crucial. There are many tricks for the dialysis of small volumes. These include placing a sample in a centrifuge tube with a hole in the cap covered with dialysis tubing; the tube is inverted and the sample dialyzed before being recovered in the tube by gentle centrifugation. The large volume of a dialyze makes its analysis impractical, while centrifugal partition allows examination of both retentate and filtrate to confirm that there is neither loss of desired material nor retention of undesired material.
### 3.3 Estimation of Glycosaminoglycan Abundance

GAG abundance may be estimated, following isolation or while still attached to a PG, by an assay relying upon the interaction of the GAGs and a dye. The GAG–dye complex may be precipitated and the amount of dye present estimated, or a change in absorbance of the complex quantified. It is important to note that with the exception of the method of Bjornsson\(^{[43]}\), the response from each GAG is different. Following depolymerization GAGs show no response but if appropriate controls are used responses will remain linear.

#### 3.3.1 Alcian Blue Solution Method\(^{[44]}\)

In this method 100 µL of sample is mixed with 1.2 mL of fresh 1.4 mg mL\(^{-1}\) alcian blue in 0.5 M sodium acetate and the absorbance is determined at 480 nm after 10 min. This assay is not very sensitive and suffers from interference from high levels of salt, but it is very rapid and is linear from 10 to 100 µg mL\(^{-1}\).

#### 3.3.2 Alcian Blue Precipitation Assay I\(^{[45]}\)

This assay involves the precipitation of an alcian blue–GAG complex and subsequent dissociation of the dye using surfactants. It is possible to use MgCl\(_2\) in a critical electrolyte concentration technique to prevent the binding of certain GAGs,\(^{[46]}\) although at low concentrations all GAGs will bind.

To 1 mL of freshly prepared centrifuged dye solution (0.05% alcian blue in 50 mM sodium acetate–50 mM MgCl\(_2\); pH 5.8) is added 20 µL of sample (1–10 µg). After 2 h at ambient temperature the mixture is centrifuged at 2000 g for 10 min, then the pellet is washed in 2 mL of ethanol and resuspended in 1 mL of 10% SDS in 50 mM sodium acetate (pH 5.8) and the absorbance is measured at 620 nm.

#### 3.3.3 Alcian Blue Precipitation Assay of Bjornsson\(^{[43]}\)

Bjornsson has published an alcian blue precipitation assay with increased sensitivity (10–800 ng in 10 µL) which, as interference from proteins is minimized, is suitable for the analysis of PGs and GAGs in urine and blood. Significantly this method has the important feature that a single, parabolic, standard curve will allow the estimation of all sulfated GAGs.

Samples (10 µL) are added to a microtiter plate well, 20 µL of 1:1 8 M GuHCl: reagent A (54 mM H\(_2\)SO\(_4\)–0.75% Triton\(^{TM}\) X-100) is added and the mixture shaken for 15 min. To each well is added 200 µL of reagent B (5% alcian blue stock (stock is alcian blue dissolved in 18 mM H\(_2\)SO\(_4\)–0.4 M GuHCl such that a 1% solution has an absorbance of ca. 1.4 at 600 nm) in 18 mM H\(_2\)SO\(_4\)–0.25% Triton\(^{TM}\) X-100; stable for 1 month). After shaking for 1 h, 200 µL of the mix is transferred to a dot-blot apparatus and drawn through a washed and blocked PVDF (poly(vinylidene difluoride)) membrane. Each well is washed twice with 200 µL of 50% ethanol in 5 mM MgCl\(_2\) and the membrane is air dried. The blot is quantified with image analysis software and a conventional document scanner using RGB (red–green–blue) mode with two pieces of clear plastic below the blot. Note that several standards are required as differences in density are recorded at different positions across the scanning arm.

#### 3.3.4 Safranin O\(^{[47]}\)

A 50-µL aliquot containing ca. 10–100 ng of sample is placed on the side of a dot-blot apparatus well and 400 µL of 0.02% safranin O in 50 mM sodium acetate at pH 4.75 is added with the vacuum applied. The mixture is drawn through a washed PVDF membrane and following two washes with water and methanol the OD of the precipitate is determined at 490 nm.

#### 3.3.5 1,9-Dimethylmethylene Blue (Taylor’s Blue) Assay\(^{[48]}\)

The dye is prepared by adding 16 mg of DMB to 5 mL of ethanol and subsequently adding this to 995 mL of water containing 2 g of sodium formate and 2 mL of 90% formic acid; the low pH (3.5) prevents interference by nucleic acids. If protected from light the solution is stable for months. Samples (40 µL containing ca. 1–5 µg mL\(^{-1}\)) are added to a microtiter plate well and 250 µL of dye is added. GAGs cause a change in the dye color from blue to purple and the absorbance of the solution may be determined at either 600 nm or 535 nm. The former is more sensitive although it exhibits decreasing absorbance with increasing amounts of GAG.

#### 3.3.6 Reducing Sugar

Following depolymerization of a GAG each oligosaccharide possesses a reducing sugar in equilibrium between ring-closed and ring-open forms, and its abundance may be estimated using this sensitive assay (0–50 µM). Samples (25 µL) are mixed with 50 µL of 0.38 M sodium carbonate, 0.21 M glycine, 1.8 M copper sulfate pentahydrate and 6.1 M neocuproine HCl, then heated to 100 °C for 12 min. The solutions are cooled, diluted with 125 µL of water, centrifuged and the absorbance at 450 nm measured.
3.4 Compositional Analysis

3.4.1 Monosaccharide Analysis

Monosaccharide analysis is an important step in the preliminary identification of an unknown GAG. Samples are hydrolyzed in 0.2 mL of 4 M TFA (trifluoroacetic acid) at 95 °C for 4 h, then lyophilized. The spectrum of monosaccharides found in GAGs is relatively limited and so most general methods for monosaccharide analysis are appropriate. The analysis of unmodified sugars by HPAEC is a standard Dionex CarboPac™ PA1 application with elution in 16 mM NaOH and pulsed amperometric detection (PAD).

3.4.2 Total Sugar Assay (Orcinol)

This assay uses H2SO4 to hydrolyze glycosidic linkages and dehydrate the monosaccharides generated, which react with orcinol to give a colored product with a detection range to ca. 500 µM. Samples (200 µL) are ice cooled and 800 µL of fresh ice-cold 14 mM orcinol in conc. H2SO4 is added. Following mixing, the solution is cooled to 80 °C for 15 min and the absorbance of the cooled solution is determined at 510 nm (as used by the original authors) or 420 nm (which shows greater sensitivity). Each monosaccharide generates a different absorbance, so unknown or mixed samples must be interpreted carefully.

3.4.3 Sialic Acid by Warren Assay as Modified by Chaplin

Sialic acid is present on KS as a cap, although asialo chain caps, rare in skeletal KS, are abundant in corneal KS. Nucleic acids interfere with this assay, which requires three reagents. Reagent A is prepared by adding 58 mL of orthophosphoric acid to 4.278 g of sodium metaperiodate dissolved in 4.0 mL of water, and making the solution up to 100 mL with water. Reagent B is 0.77 M sodium arsenite–0.5 M sodium sulfate in 0.1 M H2SO4, while reagent C is 42 mM 2-thiobarbituric acid–0.5 M sodium sulfate. Reagent A (40 µL) is added to 80-µL samples (ca. 5–500 µM) and the solution is mixed, as it is after the addition of each reagent. After 20 min at ambient temperature 400 µL of reagent B is added and after a further 5 min 1.2 mL of reagent C is added. The tubes are heated to 100 °C for 15 min, then cooled and the chromophore is extracted into 1 mL of cyclohexanone. The solution is centrifuged before the absorbance of the upper layer is determined at 549 nm.

3.4.4 Uronic Acid

The repeat region of each GAG, except for KS, contains alternating uronic acid residues which may be estimated by reaction of carbazole with the hydrolyzed uronic acid. Apart from the heating step the assay should be carried out on ice; 250-µL aliquots are added, with mixing, to 1.5 mL of 950 mg of sodium tetraborate decahydrate in 100 mL of cold H2SO4 and the tubes are heated to 100 °C for 10 min. Then 50 µL of 125 mg of carbazole in 100 mL of ethanol (keep cold and protect from light and air) is added to the cooled tubes which are mixed and heated to 100 °C for 15 min after which the absorbance of the cooled samples is determined at 525 nm. Several compounds interfere with this assay, including CHAPS, neutral carbohydrates and protein. Heparin and HS also give anomalously high values.

3.4.5 Anthrone for Neutral Sugars

The assay of neutral sugars is important in the determination of KS which contains Gal but no uronic acid. Samples (1 mL containing up to 100 µg) are layered on top of 5 mL of 14.4 mM anthrone in dilute H2SO4 (500 mL H2SO4–200 mL dH2O) and then mixed after 10 min, heated to 100 °C for 10 min and the absorbance at 620 nm determined.

3.4.6 Elson–Morgan Assay for Hexosamine

The original method has been simplified by Reissig et al. and Chaplin to provide a sensitive (1–100 µM) assay. To 50 µL of 0.2 M di-potassium tetraborate tetrahydrate is added 250 µL of sample (hydrolyzed and suspended in NaOH, pH 10) and the mixture is heated to 100 °C for 3 min. After cooling 1.5 mL of reagent B is added. Reagent B is prepared by adding 1.5 mL of water to 11 mL of HCl, then adding 87.5 g of glacial acetic acid and 10 g of 4-(N,N-dimethylamino)benzaldehyde, the working solution being a 1:10 dilution of this stock in glacial acetic acid. The sample mix is kept at 37 °C for 20 min and the absorbance determined at 585 nm.

3.4.7 Assay for Sulfate Groups

An aliquot of a hydrolyzed sample is resuspended in 200 µL of dH2O and added to 3.8 mL of 0.245 M trichloroacetic acid and 1 mL of reagent A (2 g of gelatine is dissolved with heating in 400 mL of dH2O and then held at 4 °C for 6 h before 20 g of BaCl2 is added; the reagent is stable for only 1 week at 4 °C). After 15 min the absorbance is determined at 500 nm. The assay, with which phosphate interferes, is linear from 20 to 200 µg of SO4²⁻, and the standard is 104 mM potassium sulfate (10 mg mL⁻¹ SO4²⁻).
3.4.8 Assay for N-Sulfate Groups

Heparin and HS contain N-sulfated hexosamines which may be assayed by a determination of 2,5-anhydromannose, found at the reducing terminus following hydrolysis by nitric acid. Residues lacking N-sulfation are stable, therefore each oligosaccharide generated has a formerly N-sulfated residue at the reducing terminus. The principle behind this assay is also made use of for the depolymerization of GAGs (see section 3.6.1).

Reagent A is a fresh 1:20 mix of butylnitrite in ethanol; B is 2 M HCl, C is 0.11 M ammonium sulfamate, D is 5% HCl and E is 4.3 mM indole in ethanol. A sample of \(<50\,\mu\text{g}\,\text{mL}^{-1}\) uronic acid in 200 \(\mu\text{L}\) is added to 200 \(\mu\text{L}\) of reagents A and B and after 1 h at ambient temperature 200 \(\mu\text{L}\) of reagent C is added. After 1 h 1 mL of reagent D and 200 \(\mu\text{L}\) of reagent E are added, and the mixture is heated to 100°C for 5 min. After cooling 1.2 mL of ethanol is added and the absorbance at 520 nm determined.

3.5 Characterization of Intact Carbohydrate Chains

3.5.1 Nuclear Magnetic Resonance

NMR is a powerful, nondestructive technique, allowing the analysis of intact GAGs and subsequent recovery for further analysis. Because a GAG pool represents a heterogeneous population many detailed aspects of structure, particularly those from the repeat regions, will not be discernible. However information on the presence of some sugars and sulfation information may be obtained from an intact polymer. Significantly more data may be derived from a variety of two-dimensional (2-D) experiments which are essential for a full characterization.

In KS from noncorneal tissues the predominant nonreducing chain caps are \(\alpha(2-3)-\) and \(\alpha(2-6)-\) linked sialic acid, along with Gal in fetal tissues. The abundance of these caps may be determined by distinctive H3ax and H3eq doublets at ca. 1.7 and 2.7 ppm (relative to 3-trimethylsilyl[2H4]propionate) for \(\alpha(2-6)-\) linked and at ca. 1.8 and 2.8 ppm for \(\alpha(2-3)-\) linked caps. Nonreducing terminal Gal has an H1 resonance at ca. 4.55–4.56 ppm and the presence of fucose can be determined by doublets at ca. 1.17 and 5.12 ppm which represent CH3 and H1. A key signal at ca. 3.97 ppm is derived from a sulfated Gal, which along with GlcNAc signals at ca. 4.75 ppm provides a measure of sulfation in KS.

In CS the ratio of 4- and 6-sulfation may be seen from the distinctive positions of N-acetyl CH3, i.e. ca. 2.04 and 2.025 ppm respectively. If the chain has been depolymerized by an eliminase such as chondroitin ABC lyase, then the nonreducing terminal uronic acids in each oligosaccharide will have characteristic signals which report upon the sulfation of that residue and the adjacent GalNAc. The signals from H1 and H4 fall at ca. 5.19 and 5.89 ppm if the adjacent GalNAc is 0- or 6-sulfated but at 5.27 and 5.97 ppm if it is 4-sulfated. If the \(\Delta\text{UA}\) is 2-sulfated the GalNAc will be 6-sulfated and H1 and H4 fall at the distinctive positions of ca. 5.53 and 6.03 ppm respectively.

Samples need not be completely pure, although it is necessary to have significant amounts of material. However, complete \(^1\text{H}\) characterization of an octasaccharide linkage region of CS has been reported where less than 125 \(\mu\text{g}\) of sample was available.\(^{20}\)

3.5.2 Lectins

Lectins can be very useful in studies of GAGs and PGs; they do, however, often exhibit distinctive binding characteristics, so failure to bind must be carefully interpreted. A variety of lectins are commercially available and may be used in the same way as antibodies in affinity isolation of GAGs or PGs and ELISA type experiments (see section 2.6.2).

The elderberry-derived lectin \(Sambucus nigra\) agglutinin (SNA) has been shown to bind a single \(\alpha(2-6)-\) linked NeuAc chain cap strongly while having only a low affinity for the \(\alpha(2-3)-\) linked form of the chain cap, which is bound by \(Maackia amurensis II\) lectin. SNA conjugated to CL-4B has been used to isolate KS and PGs; samples are loaded in PBS and bound material is eluted with 20 mM ethylenediamine in water.

Concanavalin A, which binds \(\alpha\)-mannose residues, has been used to isolate free N-linked KS chains from a large pool of other O-linked GAGs. Materials are loaded onto an affinity column in PBS containing 5 mM Mn and Ca, both of which are required for binding, and bound chains are eluted with 200 mM \(\alpha\)-methyl mannoside.

3.5.3 Enzyme-linked Immunosorbent Assay

Free GAG chains do not bind to microtiter plate wells and so, if unmodified, must be estimated by competitive ELISA (see section 2.6.2). If an unreduced oligosaccharide is available then it may be linked to poly-L-lysine by reductive amination and this conjugate coated onto a microtiter plate well. Controls should be used to confirm that the lysine is not interacting with the GAG and masking epitopes. An example of ELISA in GAG analysis is found in the work of Karamanos et al.\(^{5}\) in which the HNK-1 epitope (3-sulfated GlcA) was examined using inhibition ELISA.

3.5.4 Electrophoresis

Electrophoretic separation of GAGs enables the analysis of several samples simultaneously and is increasing in both resolution and sensitivity. Cellulose acetate electrophoresis separates GAGs at 0.5 mA cm\(^{-1}\) for 1 h
in 100 mM pyridine–150 mM formic acid at pH 3.1.\(^{63}\) Volpi\(^{64}\) has a longer two-stage procedure using agarose gels for electrophoresis of GAG (1 mg mL\(^{-1}\)) with a sensitivity to ca. 1 µg samples in 40 mM barium acetate at pH 5.8 for 1 h at 60 mA and then in 50 mM 1,2-diamino propane with acetic acid added to pH 9 for 2 h. Following electrophoresis the gel is placed in 1% cetyltrimethylammonium bromide and stained. Volpi\(^{65}\) has also described a nitrocellulose method which allows quantification of GAGs in the 0.2–2.5 µg range. Samples are loaded onto a nitrocellulose plate which has been soaked in 0.1 M barium acetate at pH 5 for 5 min and electrophoresis is performed in the same buffer for 40 min at 20 mA. The plates are stained in 0.08% Azure A in water for 5 min and washed in water before scanning at 600 nm. Fast and slow heparin, DS, CS, and KS can be separated, although HA runs very close to DS.

### 3.6 General Techniques for Oligosaccharide Analysis

The general approach for the analysis of GAGs has conventionally involved depolymerization of the parent chain to generate oligosaccharides of manageable size and number which may be characterized. Techniques specific to a type of GAG are examined in sections 4 to 7 but there are several which have general applicability to all GAGs.

#### 3.6.1 Nitrous Acid Depolymerization

Nitrous acid depolymerizes all GAGs containing susceptible bonds by deaminative hydrolysis. N-Acetylhexosamines are not cleaved and must be de-N-acetylated\(^{66}\) by hydrazine, a reagent which is both toxic and flammable. To anhydrous KS (10 mg) and 70 mg of hydrazine sulfate catalyst is added 1 mL of anhydrous hydrazine and the mixture is heated to 98°C. After 4 h the reaction is stopped by the addition of 1 mL of dH\(_2\)O and the de-N-acetylated KS is recovered by dialysis and lyophilization. To 10 mg of de-N-acetylated KS is added 1 mL of 3.9 M NaNO\(_2\)–0.28 M CH\(_3\)COOH at pH 4.1, and after 2 h at ambient temperature the reaction is terminated by cooling on ice and raising to pH 7.5 with 2 M NH\(_4\)OH. Fucose prevents de-N-acetylation of the GlcNAc to which it is attached leaving it resistant to nitrous acid cleavage and generating a pentasaccharide, or a longer oligomer if several adjacent residues are fucosylated; linkage regions are not depolymerized, and chain caps are found as trisaccharides. Heparin and HS are de-N-acetylated in 70% hydrazine–1% hydrazine sulfate at 96°C for 6 h, which minimizes the conversion of uronic acids to hydrazides, and then depolymerized in 5.5 M sodium nitrate–0.5 M H\(_2\)SO\(_4\) for 15 h.

This method may also be used to depolymerize CS/DS chains in which case the reducing terminal residue is 2,5-anhydro-d-talose. Heparin and HS are cleaved\(^{67}\) at N-sulfated glucosamine sites by nitrous acid at pH 1.5, or following de-N-acetylation, at de-N-acetylated glucosamine at pH 4. It should be recalled that this is the basis of an assay for N-sulfated groups (see section 3.4.8). If de-N-acetylation is performed then both sites may be cleaved by treatment with nitrous acid at pH 3, generating mainly disaccharides.

During nitrous acid cleavage there is a competing ring contraction reaction, most common with heparin and HS, which prevents cleavage and generates tetrasaccharides. This is a random process which will reduce yield but have no effect upon the relative composition.

In each case the N-substituent is lost which removes the strong ultraviolet (UV) 206 nm absorbance of KS, so detection must be by electrochemical means, or by the incorporation of a label into the reducing terminal residue generated by nitrous acid cleavage.

#### 3.6.2 Labeling of Reducing Sugar

Oligosaccharide fragments generated by the action of an eliminase from CS, DS, HS or heparin have a strong absorbance at 232 nm, and KS oligosaccharides may be observed, nonspecifically, by a strong absorbance at 206 nm. However those oligosaccharides generated enzymatically by the action of animal hyaluronidases or nitrous acid depolymerization have no such chromophore.

In such cases, or to increase sensitivity, a label may be incorporated at the reducing sugar. The most commonly used methods involve the conjugation of fluorescent probes; with radiolabeling techniques there are additional hazards and requirements for monitoring.

Bigge et al.\(^{68}\) demonstrated that 2-aminobenzoic acid (2-AA) may be used to label oligosaccharides nonselectively, with high efficiency, and without the loss of either sulfoic acid or fucose. Labeling can be done using a commercial kit, which introduces fewer contaminants visible upon analysis, or the following reagents: add 150 µL of acetic acid to 350 µL of DMSO (dimethyl sulfoxide, then 120 µL of this mixture to 8.8 µg of 2-AA and 100 µL of that mixture to 11.8 mg of sodium cyanoborohydride. Labeling is performed with an anhydrous sample to which is added 1–2 µL of reagent, and the mixture is heated to 65°C. After 2 h 100 µL of dH\(_2\)O is added and the oligosaccharides are ready for analysis at \(\lambda_{ex} = 315\) nm and \(\lambda_{em} = 400\) nm.

The label modifies the chromatographic behavior of KS and CS oligosaccharides; during SEC samples are slightly retarded, although free label may elute at up to 2 column volumes beyond the total volume \(V_t\). Further, as the label carries a negative charge each oligosaccharide will be bound more tightly during IEC than without the label.
Kuster and Harvey\(^{(69)}\) reported that GAGs depolymerized in ammonium-ion-containing buffers (which are used because they are volatile) have a reduced labeling efficiency due to formation of a 1-amino sugar following cleavage which may not be labeled and was reported to occur at levels of up to 30%.

Toomre and Varki\(^{(70)}\) have labeled oligosaccharides with biotinylated aminopiryidine (BAP), a combined biotinylated fluorescent probe. While the fluorescent tag allows easy detection of the oligosaccharide, the biotin may be used to bind it to a (strept)avidin support during isolation, or to generate an affinity column for the isolation of an antibody or the examination of binding partners. The sample and 50× molar excess of BAP are lyophilized, 10µL of coupling reagent (2:1 pyridine–acetic acid) is added and the mixture is heated to 80°C. After 1 h 10µL of coupling reagent containing 1.25 mg of borane dimethyleamine is added and the mixture is reheated to 80°C for 1 h. The authors report coupling efficiencies of 40–80%, with large, highly charged oligosaccharides having the lower efficiencies.

A radilabel may be introduced by borotritide reduction with 10 mCi of Na\(^{3}H\) for 1 h prior to reduction of the remaining residues by borohydride reduction with 25 mM NaBH\(_4\) overnight.

3.6.3 Gradient Polyacrylamide Gel Electrophoresis

Gradient polyacrylamide gel electrophoresis (PAGE) on long 20–30% gels with a 5% stacking gel in a discontinuous buffer system allows the sequence and structural analysis of large oligosaccharides in a technique very similar in approach to that involving the familiar nucleic acid sequencing gels. As with all electrophoretic methods many samples can be examined simultaneously. Techniques of this sort have been used to examine the sequence of HS\(^{(71)}\) and CS.\(^{(38)}\)

A conventional resolving gel with a 20–30% gradient should be cast in 32-cm plates to give a ca. 26–28 cm resolving gel with a 5% stacking gel. Samples and standards in 10% glycerol should be loaded and a marker containing phenol red used. Using a stacking gel buffer of 25 mM TRIS·HCl at pH 6.8 and a resolving gel buffer of 192 mM glycine at pH 8.3 the samples should be run into the gel at ca. 150 V for 30 min and be resolved at 300 V until the marker approaches the bottom (ca. 15 h). Note that disaccharides may migrate slightly in advance of the marker which should be in a separate lane. Several detection methods have been reported, including Azure-A or silver staining, allowing the detection of ca. 1 ng of an oligosaccharide, or labeled oligosaccharide, to be examined. Conventional wet or semi-dry electroblotting is possible using a positively charged nylon membrane for subsequent detection by staining, fluorography or autoradiography. Alternatively the oligosaccharide may be recovered from the membrane using NaCl.

3.6.4 Fluorochrome-assisted Carbohydrate Electrophoresis

This kit-based method (http://www.glyco.com) allows the electrophoretic separation of labeled oligosaccharides of 300–3000 Da on a precast polyacrylamide gel by charge/mass ratio as well as hydrodynamic volume. Oligosaccharides are labeled with the fluorescent tag 8-aminonaphthalene-1,3,6-trisulfonic acid disodium salt (ANTS) by reductive amination, which is reported to have 95–100% labeling efficiency and to be independent of composition. Following electrophoresis the gels are imaged using either a UV light box or a charge-coupled device (CCD) imaging system. Methods based on fluorochrome-assisted carbohydrate electrophoresis (FACE) have been used for the analysis of small oligosaccharides as well as intact chains.

4 HYALURONAN

HA, discovered by Myer and Palmer in 1934,\(^{(72)}\) is composed of the repeating disaccharide \([-4]GlcA\beta(1-3)\) GlcNAcβ(1-\(C\)) \((\text{Figure 5})\) and may be up to 2 × 10\(^{6}\) Da. Although unsulfated it carries a negative charge via carboxyl groups. It is not synthesized attached to a core protein and there are no reports of any substitutions or variance in the linear sequence.

There are a variety of hyaluronidases derived from animal and microbial sources. The latter are eliminases generating oligosaccharides with a nonreducing terminal \(\Delta\)UA; in contrast those from animal sources generate a saturated product. At present only the enzyme isolated from Streptomyces hyaluronoliticus is specific for HA,\(^{(73)}\) others act upon CS while chondroitin lyases act upon HA. To digest HA to \(\sim 50000\) Da use 4 U mg\(^{-1}\) at 20°C, to digest it completely use 100 U mg\(^{-1}\) at 37°C, both in 0.1 M acetate–0.15 M NaCl at pH 5.0. If the size of the HA chain is to be estimated then EDTA and cystein should be excluded from all buffers during isolation, to prevent production of radicals which can cleave HA so reducing its size.

4.1 Estimation of Hyaluronan Abundance

Jordian et al.\(^{(73)}\) have used the specific lyase discussed in the previous section in an assay for HA. Digestion in 200 µL was terminated by the addition of 250 µL of 0.04 M NaIO\(_4\) in 0.08 N H\(_2\)SO\(_4\). After oxidation for 1 h at 37°C excess periodate was removed by addition of 0.5 mL of 3% NaAsO\(_2\) in 0.5 N HCl. After 30 min at
ambient temperature 4 mL of 0.3% thiobarbituric acid in 0.012 N HCl was added and the mixture heated to 100 °C for 15 min. Upon cooling 4 mL of 5% HCl in butanol was added and following mixing the absorbance of the butanol layer was determined at 549 nm. The authors report that this method is more sensitive than a determination of absorbance at 232 nm, and they identified 5 µg of HA in a 100-µL tissue extract.

If the HA is pure an estimation of uronic acids (see section 3.4.4) is also appropriate, but as this method is not specific for HA other GAGs, except KS, will interfere.

### 4.2 Analysis of Enzymatic Digestion Products

Price et al.\(^{(74)}\) determined the size of HA oligosaccharides up to 16mers by SEC using a Bio-Gel\(^{*}\) P-30 column eluted in 250 mM NH\(_4\)HCO\(_3\). As HA has an invariant chain the method may be reliably used to determine oligosaccharide length. The same authors also report that oligosaccharides within the same size range yielded negative-ion electrospray ionization mass spectra following analysis of a 16 µg mL\(^{-1}\) sample in 50% methanol and 0.3% Et\(_3\)N with capillary and cone voltages of 2.5 kV and 25 V respectively.

Several methods for the analysis of unsaturated CS oligosaccharides have also been calibrated for the analysis of the unsaturated HA disaccharide\(^{(75)}\) with UV and PAD detection. Karamanos et al.\(^{(76)}\) have calibrated its elution following high-performance liquid chromatography (HPLC) using an Econosphere\(^{**}\) NH2 column eluted with 5 mM sodium dihydrogen orthophosphate at pH 2.55, and also following capillary zone electrophoresis (CZE). Price et al.\(^{(77)}\) examined HA oligosaccharides up to 16mers by HPAEC using a PA1 column and acetate as eluent with PAD detection. However, the method relies on a series of isocratic elutions and a prior SEC step is required as differently sized oligosaccharides coelute. Lauder et al.\(^{(78)}\) also reported an HPAEC method using a PA1 column for the analysis of HA oligosaccharides up to 16mers which uses the same elution conditions as the analysis of CS repeat region\(^{(78)}\) and linkage region\(^{(79)}\) oligosaccharides (see sections 6.3.1 and 6.4).

A CarboPac\(^{™}\) PA1 column (4 mm × 250 mm) maintained at 30°C is eluted at 1 mL min\(^{-1}\); a 12-min isocratic period of 98% 0.1 M NaOH–2% 1.3 M NaCl in 0.1 M NaOH was followed by a linear gradient of 2–46% 1.3 M NaCl in 0.1 M NaOH over 50 min; 46–87% 1.3 M NaCl in 0.1 M NaOH over 8 min and subsequently 87–100% 1.3 M NaCl in 0.1 M NaOH over 6 min followed by a 4-min isocratic phase of 100% 1.3 M NaCl in 0.1 M NaOH. The eluted oligosaccharides were monitored on-line by absorbance at 232 nm, and the elution times are reported in Table 2.

Toffanin et al.\(^{(80)}\) reported the complete assignment of \(^{1}H\) and \(^{13}C\)-NMR spectra for HA di- and tetrasaccharides prepared by bovine testicular hyaluronidase.

### 5 KERATAN SULFATE

KS is based upon a repeating sequence of −3Galβ1-4 GlcNAcβ1− which is usually sulfated on C(6) of GlcNAc, and further sulfate groups may be present on C(6) of Gal\(^{(81)}\) (Figure 2 and Figure 5). Classification is based upon the type of linkage to the protein and the presence of specific structures. N-linked KS, originally isolated from cornea although now known to be present in cartilage,\(^{(7)}\) is termed KS-I, while that which is O-linked is KS-II.\(^{(82)}\) A third type, which is O-linked from mannose to serine or threonine, has been isolated from brain tissue.\(^{(83)}\) Types I and II are further split based upon the presence of α(2-6)-linked NeuAc chain caps and fucose α(1-3)-linked to GlcNAc, both of which are present in articular but not nonarticular cartilage.\(^{(84,85)}\) Lauder et al.\(^{(85)}\) and Brown et al.\(^{(86)}\) demonstrated for N- and O-linked chains respectively that the abundance of these tissue-specific structures is age-dependent, being absent in fetal and young tissue but appearing during maturity. Where fucose is present the Gal on the reducing side of the fucosylated GlcNAc may or may not be sulfated, while that on the nonreducing side is never sulfated. The length of KS chains is highly variable, having been reported as up to 46 disaccharides in cornea\(^{(54,87)}\) and as short as 6–10 disaccharides in fibromodulin.\(^{(7–10)}\) Corneal KS has a

5.1 Characterization

5.1.1 Size

The hydrodynamic size of an isolated KS chain, or derived oligosaccharide, may be determined by SEC on a TSK
30–30 column eluted at 30 °C in 0.2 M NaCl at 0.5 mL min
–1. 88 The Kav is determined and Equation (1) used to determine Mf. The method is valid for linear KSs with a Kav of between 0.15 and 0.65, but sialic-acid-containing oligosaccharides behave anomalously.

\[ \log_{10} M_f = 4.588 - 2.128K_{av} \]  

5.1.2 Enzyme-linked Immunosorbent Assay and Antibodies

There are several anti-KS antibodies available, of which 5D4 and others of a similar type are the most common. They recognize a highly sulfated region of KS, 55,89 which comprises a small but variable percentage of the total KS chains. 7–9 The KS from mice (in which these antibodies are raised) and also from brain has a low level of sulfation and is not highly immunogenic with respect to 5D4 types of antibody, therefore estimation of KS by this method is not always appropriate.

5.2 Depolymerizing Keratan Sulfate

There are several methods for the depolymerization of KS (Figure 2, Table 3) which have been reviewed in depth by Brown and Nieduszynski 87 (see also section 3.6.1).

5.2.1 Endo-β-Galactosidase (EC 3.2.1.103)

Endo-β-Galactosidases, from Escherichia freundii, 90 Flavobacterium keratolyticus 91 and Bacteroides fragilis, 92 hydrolyze any poly-N-acetyllactosamine chain, not just that of KS, at β(1-4) glycosidic linkages in which both the Gal and GlcNAc are unsubstituted (Figure 2). 93

Most KSs have a high level of GlcNAc sulfation and thus there are few cleavage sites, so oligosaccharides generated may be large and heterogeneous. However, if the KS has significant levels of unsulfated residues, then smaller oligosaccharides will be observed. Depolymerization should be carried out in 0.1 M TRIS·HCl at pH 7.2 with 0.1 U mg
–1 of KS at 37 °C for 24 h.

5.2.2 Keratanase (EC 3.2.1.103)

Keratanase, an endo-β-galactosidase from Pseudomonas sp., 94 will cleave β(1-4) glycosidic linkages in which the Gal is unsulfated and the GlcNAc is sulfated but unfucosylated (Figure 2). This enzyme differs from other endo-β-galactosidases in its requirement for a sulfated GlcNAc, resulting in the cleavage of most KS chains.

Following depolymerization in 0.2 M sodium acetate at pH 7.2 with 1 U per 2.3 mg of KS at 37 °C for 24 h, a range of oligosaccharides are generated each with an unsulfated Gal at the reducing terminus. As the enzyme is inhibited by Gal(6S) the internal Gal residues will, with the exception of an unsulfated disaccharide, be fully sulfated unless fucose is present. Fucose inhibits the enzyme (Figure 2) and the oligosaccharide generated will have an unsulfated Gal on the nonreducing side of the fucosylated GlcNAc (Table 4).

A sialidase contaminant has been identified in keratanase and 5 mM 2,3-dehydro-2-deoxy-N-acetyleneuraminic acid should be used to inhibit sialic acid loss; any asialo caps generated will have an odd number of residues. 7 Keratanase has been used to examine O- and N-linked KSs, 7 the oligosaccharides generated being isolated by HPLC using a Nucleosil 5SB eluted in 0–0.5 M LiCLO4 at 2 mL min
–1 and detection by absorbance at 206 nm. Work by Tai et al. 54 has resolved a series of corneal KS oligosaccharides of up to 46 disaccharides by this method.

5.2.3 Keratanase II (EC Not Defined)

Keratanase II from Bacillus sp. 93 cleaves KS at a sulfated GlcNAc, fucosylated or not, adjacent to a sulfated or unsulfated galactose (Figure 2) at 0.002 U mg
–1 KS in 10 mM sodium acetate at pH 6.8 at 37 °C for 30 h. The enzyme, which cannot act on a tetrasaccharide 87 yielding di- and tetrasaccharides from the repeat region and tri- and pentasaccharide caps, has been used to characterize N-linked 7–10 and O-linked 87,95 KSs from various sources.

5.3 Disaccharide Analysis

The disaccharide composition of KS is best determined by analysis of the oligosaccharides generated by nitrous acid cleavage which principally generates disaccharides.

larger oligosaccharides occurring only if fucose is present. However, it should be recalled that the oligosaccharides have no absorbance at 206 nm and must be detected by electrochemical means or through the introduction of a label. Brown et al.95) examined KS from articular cartilage in this way, the oligosaccharides being radiolabeled by borotritide reduction and eluted from a Nucleosil75 5SB column with a gradient of 2 mM to 0.5 M LiClO4. Alternatively the sample may be applied to an AS4A-SC column and eluted at 1 mL min⁻¹ with a 5-min isocratic period of 50 mM NaOH and then in a gradient of 0–0.75 M sodium acetate over 30 min with constant 50 mM NaOH.

### 5.4 Fingerprinting Keratan Sulfate

For the full analysis of KS structure, keratanase II digestion is the best method for depolymerization; caps, linkage regions and repeat regions are found in a small number of oligosaccharides from which fucosylation, sialylation and sulfation levels may be determined. Digestion of a PG with the KS still attached results in only cap and repeat region oligosaccharides being generated, the linkage region remaining attached to the core protein.

Oligosaccharides have been examined by IEC on a Spherisorb® 5S column with a gradient of 2–250 mM LiClO4 and UV detection at 206 nm (Figure 6). This technique is sensitive and has good enough resolution that an analytical column may be used to fingerprint the oligosaccharides. However, the method requires long run times and lacks the excellent reproducibility of the Dionex AS4A-SC column, which, allied with PAD detection, allows the sensitive detection of unlabelled oligosaccharides. A 20-µL aliquot of reduced oligosaccharides is applied to a Dionex AS4A-SC column (4 mm × 250 mm) at 30 °C and running at 1 mL min⁻¹. The eluent is monitored by PAD and oligosaccharides eluted by a 5-min isocratic period of 5% 1 M NaOH—95% water, followed by a linear gradient of 0–95% 1.5 M sodium acetate and constant 5% NaOH over 50 min. The PAD used program: 0.00 s, 0.10 V; 0.50 s, 0.10 V; 0.51 s, 0.60 V; 0.59 s, 0.60 V; 0.60 s, −0.60 V; 0.65 s, −0.60 V, integration.

### Note

- **Peak Code** represents the sequence of the oligosaccharide.
- **Oligosaccharide** describes the structure of the oligosaccharide.
- **Reduced Elution time (min)** indicates the time it takes for the oligosaccharide to elute.
- **Relative molar response** indicates the sensitivity of the method.
- **Fluorescent label Elution time (min)** indicates the time it takes for the fluorescent label to elute.

This table provides a comprehensive overview of the elution positions of KS oligosaccharides generated by keratanase II digestion.
Figure 6 Strong anion exchange HPLC analysis of a keratanase II digest of KS. An aliquot (20 µL) of reduced oligosaccharides derived by keratanase II digestion of the KS attached to tracheal cartilage fibromodulin was applied to a Spherisorb 5S column and eluted at 1 mL min⁻¹ in a gradient of 2–250 mM LiClO₄ with UV detection at 206 nm. The KS was depolymerized while attached to the PG and hence no linkage regions are observed. For oligosaccharide codes see Table 4.

being 0.3–0.5 s. A sample chromatogram is shown in Figure 8 and the elution times are given in Table 4. The method allows the detection of ca. 10 ng of a single oligosaccharide and resolves α(2-3)- and α(2-6)-linked sialic acid caps, as well as fucosylated oligosaccharides. However, PAD suffers from a nonmolar response; for fully quantitative data, response factors must be determined for each oligosaccharide examined.

Whitham et al. have developed a fingerprinting method for keratanase II oligosaccharides labeled with the fluorescent probe 2-AA (see section 3.6.2). An aliquot is applied to a Dionex AS4A-SC column at 50 °C and eluted at 2 mL min⁻¹. After 5 min of constant 150 mM NaOH, bound oligosaccharides are eluted by a gradient of 0–600 mM NaCl with constant 150 mM NaOH over 60 min. A sample chromatogram is shown in Figure 8 and the elution times are given in Table 4. The same protocol has been employed by Lauder et al. for fingerprinting of CS linkage and repeat regions (see sections 6.3 and 6.4), allowing a coordinated approach to the analysis of KS and CS.

6 CHONDROITIN SULFATE/DERMATAN SULFATE

The repeat region of CS comprises a repeating disaccharide —4)GlcAβ(1-3)GalNAcβ(1—, while in DS D-GlcA is replaced by L-IdoA through epimerization at C(5) (Figures 3, 5 and 7). In mammals CS may be sulfated on C4 and/or C6 of GalNAc and C2 of GlcA. Variations found elsewhere include sulfation on C3 of GlcA residues and fucosylation of GalNAc. In DS the sulfation pattern is much simpler, with GalNAc being

![Figure 7 Structural models for CS/DS.](image-url)
almost 100% 4-sulfated. Although the functions of these GAGs are yet to be fully elucidated, it is known that CS has a role in articular cartilage where the osmotic swelling it causes helps load bearing. Other data suggest a more direct role in macromolecular interactions; it has been shown\(^{99,100}\) that the expression of some CS epitopes in the rodent is developmentally regulated and chondroitin 4-sulfate has a role in the cytoadherence of malaria infected red blood cells,\(^{101}\) the adherence of the malaria parasite to human placenta\(^{28}\) and the regulation of neurite outgrowth.\(^{102}\) There is evidence that a CS PG, appican, has a role in Alzheimer’s disease\(^{103}\) and DS has been shown to bind to the growth promoter spermine.\(^{30}\)

A sulfated GalNAc has been shown to be the major nonreducing terminal residue of swarm rat chondrosarcoma CS,\(^{104}\) 85–90% of chains isolated were capped by either GalNAc4S or GalNAc4,6S. However, there are very significant age and pathology related changes in the
abundance of GalNAc4,6S in human articular cartilage aggrecan: it is almost absent in fetal tissue while terminating ca. 60% of chains in the normal adult but only ca. 30% in osteoarthritic cartilage; GalNAc4,6S is very rare within the repeat region.

There are reports of Gal sulfation in the linkage region of CS isolated from aggrecan of shark cartilage, bovine nasal septum and articular cartilage and swim rat chondrosarcoma. Moses et al. determined that during the elongation of the linkage region there is transient xylose phosphorylation, as observed in CS from swim rat chondrosarcoma, but that this ester is cleaved after elongation of the linkage region to a trisaccharide but prior to elaboration of the complete CS chain. The repeat region close to the linkage region has a higher than average incidence of unsulfated and 4-sulfated GalNAc residues.

Given the range of sulfation possibilities there are a very large number of potential CS disaccharides, hexa- and hexaxasaccharides (n = 512). Including C(5) epimerization to IdoA rather than glucuronic acid, i.e. 1-Ido(1-3)Galβ(1-3)Galβ(1-4)Xyl.

6.1 Characterization

6.1.1 Iduronic Acid Levels

Karamanos et al. devised a method for the determination of IdoA and GlcA levels in CS/DS chains, avoiding the serious losses normally associated with hydrolysis. The uronic acids are converted to their corresponding neutral sugars, glucose and 1,6-anhydroidose which are stable during hydrolysis. The GAG is mixed with 1 mg of 106 µL of pyridine containing 10% benzoic anhydride and 5% 4-dimethylaminopyridine at 37°C for 90 min. Following the addition of 4.5 mL of water the sample was desalted on a Sep-Pak C18 column washed with 10 mL of 10% pyridine in water and 5 mL of water and the sugars were eluted with 2.5 mL of acetonitrile. Laufer et al. have quantified the unmodified Glc and 1,6-anhydrohexose derived from the parent chain by hydrolysis, using HPAEC on a PA1 column with PAD under the same conditions used for monosaccharide analysis (see section 3.4).

6.2 Specificity of Enzymes Acting Upon Chondroitin Sulfate/Dermatan Sulfate

There are a number of enzymes which act upon CS/DS, either to depolymerize or to specifically remove sulfate esters (Figure 3). The naming of CS/DS lyase enzymes is partly based on a historical nomenclature whereby 4-sulfated CS was termed CS(A), 6-sulfate was termed CS(C) and DS was CS(B). Each lyase has a slightly different specificity but all fail to cleave a highly sulfated CS; specifically a bond between a 4- and 6-sulfated GalNAc and a 2-sulfated GlcA is resistant (Figure 3).

If highly sulfated CS is present SEC will allow the isolation of larger resistant regions of the chain for further analysis. Chondroitin ABC lyase will cleave both CS and DS; all oligosaccharides, except the cap, will have a nonreducing terminal ΔUA, removing the distinction between CS and DS at this residue. An IdoA will only be cleaved by a B lyase and not by A or C lyase. Oligosaccharides generated by the eliminase action of a chondroitin lyase have a strong chromophore at 232 nm derived from the C(4) C(5) unsaturated bond of the ΔUA residue; molar extinction coefficient = 5500. This value is similar, but not identical, for all oligosaccharides and allows sensitive detection without further modification.

6.2.1 Chondroitin ABC Lyase (EC 4.2.2.4)

Hamai et al. identified two chondroitin ABC lyase activities, corresponding to an endo- and an exolyase, the endolyase being unable to cleave tetrasaccharides, whereas the exolyase can (Figure 3). These workers identified the Seikagaku Corporation protease free product as possessing solely the endolyase activity, enabling this enzyme to be used to generate tetrasaccharides from a limit digest. Both enzymes can cleave chondroitin 4- and 6-sulfate as well as DS and unsulfated GalNAc. The activity towards the 4-sulfate is, however, significantly higher than that towards 6-sulfate, resulting in the preferential localization of 4-sulfated GalNAc residues at the reducing end of the resulting oligosaccharides.
Sugahara et al.\(^{97}\) determined that digestion with chondroitin ABC lyase will remove any GlcA 3-sulfate groups; to obtain oligosaccharides containing this structure testicular hyaluronidase must be used. Sugahara et al.\(^{122}\) also determined that the enzyme will preferentially remove the nonreducing terminal disaccharide from a free hexasaccharide. To digest GAGs to completion use 0.01 U mg\(^{-1}\) CS at 37 °C for 24 h in 0.1 M TRIS · HCl at pH 8.

### 6.2.2 Chondroitin AC Lyase (EC 4.2.2.5)

There are three chondroitin AC lyases: ACI from Flavobacterium heparinum, ACII from Arthrobacter aurescens and ACIII from Flavobacterium sp. Hp102. Unlike chondroitin ABC endolyase these enzymes have no size restrictions on their activity. However, they differ in their ability to cleave bonds to different disaccharides; ACIII cannot cleave a bond to GlcA-GalNAc4,6S or GlcA2S-GalNAc6S, ACI can cleave the former but not the latter (Figure 3), and ACII is able to act upon both bonds, but not a very highly sulfated CS. Digestion should be performed using 0.1 U mg\(^{-1}\) in TRIS · HCl at pH 8 for 24 h at 37 °C.

### 6.2.3 Chondroitin 2-, 4- and 6-Sulfatase

These enzymes specifically remove a sulfate ester from C(2) of a uronic acid, and C(4) or C(6) of a GalNAc residue, respectively (Figure 3). The latter acts solely on the reducing terminal GalNAc\(^{122}\); while chondroitin 4-sulfatase alone also acts upon the adjacent internal GalNAc residue. However, the 4-sulfatase will not act upon a GalNAc4S,6S residue, while chondroitin 6-sulfatase will if it is located at the reducing terminus of an oligosaccharide.\(^{122}\) Digestion is often performed to examine the structure of an unknown oligosaccharide and may be performed at 1 mU mmol\(^{-1}\) in a minimum volume (ca. 20 µL) of TRIS · HCl at pH 8 for 20 min at 37 °C.

### 6.2.4 Other Enzymes

Both CS B and C lyase are commercially available and cleave only DS and GalNac(6S) respectively. HA lyase also cleaves CS, but at a lower rate than HA.

### 6.3 Disaccharide Analysis

A determination of the disaccharide composition of CS/DS will show levels of GalNAc 4- and 6-sulfation along with uronic acid sulfation; rarer structures such as Δdi-4,6S and Δdi-0S will be observed, but there will be no information about their position within the chain.

There are many techniques for the analysis of the disaccharides generated following depolymerization of CS by chondroitin ACII or conventional ABC lyase, and several methods of detection, including the use of absorbance at 232 nm, fluorescent labeling and PAD (Table 5). Midura et al.\(^{75}\) calibrated an HPAEC method using a CarboPac™ PA1 column with elution in TFA and detection by PAD. However, detection by PAD suffers from diminishing response with increasing sulfation, the trisulfated disaccharide Δdi-tris being undetectable.

Karamanos et al.\(^{76}\) reported an extensive examination of 24 disaccharides, including 3-sulfated GlcA, from CS, DS and HA by HPLC on an Econosphere™ NH2 column with UV detection at 231 nm. Elution was by a series of isocratic eluents: 5 mM sodium dihydrogen orthophosphate, pH 2.55, for nonsulfated; 50 mM sodium dihydrogen orthophosphate, pH 2.50, for monosulfated; and 50 mM sodium sulfate—10 mM sodium acetate, pH 5.0, for di- and trisulfated disaccharides.

| Table 5 Methodologies used for analysis of CS/DS |
|-------------------------------------------------|---------------------------------|------------------|------------------|
| Depolymerization method                         | Maximum size                   | Separation method | Detection method |
| Repeat region                                   |                                 |                  |                  |
| ABC endolyase\(^{78}\)                          | Hexasaccharide                 | HPAEC            | 232 nm           |
| ABC endolyase\(^{97}\)                          | Hexasaccharide                 | HPAEC            | Fluorescence     |
| ACII\(^{123}\)                                  | Disaccharide                   | HPLC, ion pair   | 232 nm           |
| ACII\(^{123}\)                                  | Disaccharide                   | HPLC, IEC        | 232 nm           |
| ACII, hyaluronidase\(^{124}\)                   | Tetrasaccharide                | HPLC, IEC        | Fluorescence     |
| ACII, hyaluronidase\(^{124}\)                   | Tetrasaccharide                | HPCE             | 232 nm           |
| Caps                                            |                                 |                  |                  |
| ACII lyase\(^{106,107}\)                        | Disaccharide                   | HPAEC            | Fluorescence     |
| Linkage region                                  |                                 |                  |                  |
| ABC endolyase\(^{79}\)                          | Octasaccharide                 | HPAEC            | 232 nm           |
| ABC endolyase\(^{37}\)                          | Octasaccharide                 | HPAEC            | Fluorescence     |
Figure 9 HPAEC analysis of CS oligosaccharides. An aliquot (20 µL) of chondroitin ABC endolyase digested CS was applied to (a) a Dionex CarboPac™ PA1 column (250 mm × 4 mm) maintained at 30°C. Elution was at 1 mL min⁻¹; a 12-min isocratic period of 98% eluant A (0.1 M NaOH)–2% eluant B (1.3 M NaCl in 0.1 M NaOH) was followed by a linear gradient of 2–46% eluant B over 50 min, 46–87% eluant B over 8 min, and 87–100% eluant B over 6 min followed by a 4-min isocratic phase of 100% eluant B. The eluant was monitored by absorbance at 232 nm. (b) The aliquot was applied to a Dionex AS4A-SC column maintained at 50°C running at 2 mL min⁻¹ with 150 mM NaOH and after 5 min of isocratic elution a gradient of 0–600 mM NaCl over 60 min and fluorescent detection at λ_ex = 315 nm and λ_em = 400 nm.
Table 6  Elution positions of CS/DS oligosaccharides following HPAEC. The elution positions of CS/DS oligosaccharides are shown following analysis using the Dionex-based PA1 or AS4A-SC methods described with UV or fluorescent detection respectively. See Figure 9 for chromatography conditions.

Oligosaccharides containing GlcA 3-sulfation and N-sulfated GalNAc were examined. A linear response was observed to 50 µg, with the detection limits being 58 ng for unsulfated, 8–11 ng for monosulfated, 12–15 ng for disulfated, and 25–30 ng for trisulfated disaccharides.

Karamanos et al. (77) reported a high-performance capillary electrophoresis method for the analysis of disaccharides from vertebrate CS, DS and HA, i.e. no 3-sulfated GlcA. The method allows a complete determination of the disaccharide profile within 14 min on a fused-silica capillary in 15 mM sodium dihydrogen orthophosphate, at pH 3, using reversed polarity at 20 kV with detection at 232 nm. Concentrations of 32 pmol L⁻¹ (22 ng L⁻¹) were detectable and the method has been used to examine HA in human malignant mesothelioma. (125)

Karamanos et al. (135) also reported an ion pair method for the analysis of CS, DS and HA disaccharides. Using tetrabutylammonium as the ion-pair agent the oligosaccharides are analyzed by using a conventional reversed-phase column with elution in acetonitrile. Many laboratories have such columns in use, whereas an ion-exchange column may not be available.

Lauder et al. (78) reported an HPAEC method for disaccharide analysis of CS/DS chains, using a Dionex CarboPac™ PA1 column and an elution protocol identical to that used for longer oligosaccharides, linkage regions (see section 6.4) and HA oligomers (see section 4.2) with detection at 232 nm. Two fluorescent-based HPAEC methods have been reported for disaccharides (126) and di- and tetrasaccharides. (37) The former labels with 2-amino-pyridine and affects separation on an AS4A-SC column in a gradient of 0–500 mM sodium trifluoroacetate. The latter labels with 2-AA (see section 3.6.2) and separates on an AS4A-SC column maintained at 25°C running at 2 mL min⁻¹ with 5 min of constant 150 mM NaOH after which bound oligosaccharides are eluted by a gradient of 0–600 mM NaCl with constant 150 mM NaOH over 60 min. A chromatogram is shown in Figure 9 and the elution times are reported in Table 6.

6.3.1 Longer Oligosaccharides

The methods reported above for disaccharide analysis can provide no information about larger blocks of structure. However, Lauder et al. (78) have reported an HPAEC method for the analysis of di-, tetra- and hexasaccharides derived from CS/DS chains. A CarboPac™ PA1 column (4 mm × 250 mm) maintained at 30°C was eluted at 1 mL min⁻¹; a 12-min isocratic period of 98% 0.1 M
NaOH–2% 1.3 M NaCl in 0.1 M NaOH was followed by a linear gradient of 2–46% 1.3 M NaCl in 0.1 M NaOH over 50 min; 46–87% 1.3 M NaCl in 0.1 M NaOH over 8 min and subsequently 87–100% 1.3 M NaCl in 0.1 M NaOH over 6 min followed by a 4-min isocratic phase of 100% 1.3 M NaCl in 0.1 M NaOH; the eluted oligosaccharides are monitored by absorbance at 232 nm. A chromatogram is shown in Figure 9 and the elution times are reported in Table 6.

For fluorescently labeled oligosaccharides of tetrasaccharide and longer the method of Whitham et al.\textsuperscript{96} has been adapted and the elution conditions are those

![Figure 10 HPAEC analysis of CS linkage regions. An aliquot (20 µL) of CS linkage regions of (a) hexasaccharide and (b) octasaccharide size was applied to a Dionex CarboPac\textsuperscript{™} PA1 column and eluted as described for repeat region oligosaccharides (Figure 9). The oligosaccharide code is in Table 7.](image)
Table 7 Elution positions of linkage region oligosaccharides following HPAEC. The elution positions of CS linkage region oligosaccharides are shown following analysis using the Dionex-based PA1 or AS4A-SC methods described with UV or fluorescent detection respectively. See Figure 10 for chromatography conditions.

PROTEOGLYCAN AND ACIDIC POLYSACCHARIDE ANALYSIS

Figure 11 HPAEC analysis of fluorescently labeled CS linkage regions. An aliquot (1 µL) of hexasaccharide CS linkage regions released unreduced with LiOH and fluorescent labeling was applied to an AS4A-SC column eluted as described for fluorescently labeled repeat region oligosaccharides (Figure 9). The oligosaccharide code is in Table 7.

described previously for disaccharides, i.e. AS4A-SC column maintained at 50 °C running at 2 mL min⁻¹ with 5 min of constant 150 mM NaOH after which bound oligosaccharides are eluted by a gradient of 0–600 mM NaCl with constant 150 mM NaOH over 60 min. A chromatogram is shown in Figure 9 and the elution times are reported in Table 6.

6.4 Linkage Region Analysis

The linkage regions of CS/DS have the general structure GlcAβ(1-3)Galβ(1-3)Galβ(1-4)Xylβ1-O-Ser,(127) although the GlcA may be replaced by IdoA in DS. This tetrasaccharide may be isolated, following chondroitin ACII lyase digestion, by SEC to separate it from repeat region disaccharides (Figure 3). Hexasaccharide linkage regions, retaining the first repeat region disaccharide, have been isolated following digestion with conventional chondroitin ABC lyase which is unable to cleave the bond between the disaccharide and the linkage region.(107) Other workers(79) have isolated octasaccharide linkage regions by digestion with chondroitin ABC endolyase. Although this enzyme cannot cleave an isolated tetrasaccharide,(121) it is able to cleave an isolated octasaccharide linkage region to yield a di- and a hexasaccharide.(79) The isolation of octasaccharide linkage regions may rely upon steric hindrance as digestion is performed prior to the release of the CS linkage region.(79)

Following digestion and subsequent release by β-elimination the linkage region should be parsed by SEC to allow it to be separated from smaller oligosaccharides. This step is crucial as two octasaccharide and two hexasaccharide linkage regions, along with a disaccharide, all elute within 1 min upon HPAEC (Figure 10, Tables 6 and 7). Alternatively, following digestion and reduction the linkage regions may be released unreduced in 0.5 M LiOH(36) and can then be fluorescently labeled (Figure 11 and Table 7).

The methods used for fingerprinting the linkage regions, labeled or not, are those used for the analysis of the di- tetra- and hexasaccharides derived from the repeat region; a Dionex CarboPac™ PA1 column with UV detection at 232 nm or a AS4A-SC column and detection by fluorescence(37,78,79) (see sections 6.3 and 6.3.1).

6.5 Analysis of Chain Caps

Plaas et al. examined CS chain caps by HPAEC on a Dionex AS4A-SC column following fluorescent labeling of the chondroitin ACII and ABC lyase generated oligosaccharides.(105,106) Capping oligosaccharides are not modified by the action of these eliminases and therefore, unlike other oligosaccharides present, do not possess a strong absorbance at 232 nm. The 2-aminopyridine labeled oligosaccharides were examined by HPAEC on an AS4A-SC column eluted with a gradient
of 0–500 mM sodium trifluoroacetate. The major caps, GalNAc4,6S and GalNAc4S, were found to occur as the monosaccharides and were eluted at unique positions. However, the more minor caps, GlcAβ(1-3)GalNAc4S and GlcAβ(1-3)GalNAc6S, co-eluted with Adi-4S and Adi-6S. Prior treatment with mercuric acetate\textsuperscript{(21)} to remove the terminal Δ4,5-unsaturated uronic acids from these repeat region disaccharides, yielding two monosaccharides, leaves the saturated caps in their native state, allowing their subsequent chromatographic quantification.

### 7 HEPARAN SULFATE/HEPARIN

Of all the GAGs heparin and HS have the greatest structural complexity and they have received attention in several comprehensive reviews\textsuperscript{(128–130)} They have been extensively studied because of the anticoagulant functions of heparin and the interactions of HS with various growth factors. They comprise a repeating disaccharide \(-4\)GlcNAc(1-4)uronic acid(1– in which the uronic acid may be GlcA or IdoA with the possibility of IdoA 2-sulfation and GlcNAc N- and 6-sulfation, although there is little GlcA 2-sulfation or GlcNAc 4-sulfation. HS consists primarily of unsulfated GlcA residues and GlcNAc 6- or N-sulfation. Heparin is structurally similar to HS but is more highly sulfated, the trisulfated disaccharide \(-4\)GlcNS6Sα(1-4)IdoA2Sα(1– often accounting for 80–90% of the chain, depending on tissue source. They are both linear GAGs, without fucosylation or other branching. In CS there is evidence that not all potential combinations of structure are found in vivo, but there is no such evidence for HS/heparin in which a wide variety of structures have been observed.

#### 7.1 Characterization

##### 7.1.1 Depolymerization of Heparin and Heparan Sulfate

Although chondroitin ACII lyase may be used to generate disaccharides from CS, no single enzyme is capable of this for HS/heparin, and even the use of all three enzymes described next does not always result in complete depolymerization. There is some confusion in the nomenclature used and care must be taken when sourcing these enzymes; full details of specificity and the temperature for maximal activity should be sought from the suppliers.

Heparinase I/Heparitinase III (EC 4.2.2.7) cleaves regions of high sulfation, acting on GlcNS(±6S±3S)α(1-4)IdoA2S. Heparinase II/Heparitinase II (no EC number assigned) will cleave either GlcA or IdoA containing disaccharides GlcNR(±6S)α(1-4)GlcA/IdoA, but not unsulfated disaccharides. Heparinase III/Heparitinase I (EC 4.2.2.8) shows specificity for regions of low sulfation and will cleave GlcA-containing disaccharides irrespective of the sulfation status of the glucosamine GlcNR(±6S)α(1-4)GlcA.

#### 7.1.2 Disaccharide Analysis

Nitrous acid depolymerization, with or without prior hydrazinolysis, yields mainly disaccharides. Following hydrazinolysis the entire chain may be depolymerized; however, without this treatment only N-sulfated regions will be susceptible to nitrous acid treatment. Importantly for these GAGs this method retains GluA/IdoA differentiation although N-sulfation is lost. The reverse is true of enzyme depolymerization in which both uronic acids are converted to a ΔUA, absorbing strongly at 232 nm, but N-sulfation is retained.

The requirement for all three enzymes to generate disaccharides and their differing stabilities and specificities means that they should be added sequentially to a digest. The following protocol is recommended by Lyon\textsuperscript{(128)} to a digest at 30°C add 10 mU mL\textsuperscript{-1} heparinase I and repeat the addition at 1 h; at 3 and 4 h respectively raise the temperature to 37°C and add 10 mU mL\textsuperscript{-1} of heparinase III and at 6 and 8 h add 10 mU mL\textsuperscript{-1} of heparinase II and digest overnight.

Following the depolymerization of heparin/HS to disaccharides there are several techniques for the analysis of the oligosaccharides, relying either upon the absorbance at 232 nm introduced by enzyme action or that of a label introduced at the reducing terminus. Yoshida et al.\textsuperscript{(131)} used a LiChrosorb\textsuperscript{®} NH2 column in a method also calibrated for CS/DS oligosaccharides, while Turnbull and Gallagher\textsuperscript{(132)} report a strong anion exchange method with a 120-min 0.2–2 M or 0–1 M NaCl gradient for heparin or HS respectively. Karamanos et al.\textsuperscript{(133)} reported a rapid, sensitive and accurate HPCE method for the analysis of heparin and HS. The analysis of disaccharides generated by a combination of all three enzymes is done with reversed polarity and 15 mM phosphate buffer, at pH 3.5, allowing the analysis of all 12 disaccharides by absorbance at 232 nm with detection of femtogram amounts and at the attomole level.

Karamanos et al.\textsuperscript{(134)} have also reported an ion-pair HPLC method for the analysis of heparin and HS. The analysis of disaccharides generated by a combination of all three enzymes is performed with tetrabutylammonium as the ion pairing agent on a Supelcosil\textsuperscript{®} L18 column in an acetonitrile gradient with detection at 232 nm. This method allows the analysis of ca. 2–5 ng of a single disaccharide.
7.1.3 Analysis of Longer Oligosaccharides

While the lack of a single enzyme to generate heparin/HS disaccharides makes disaccharide analysis more complex, the different specificities of the three enzymes allow the isolation of oligosaccharides, hexasaccharide and longer, of defined disaccharide composition which varies with the enzyme used. Following the digestion of heparin/HS to generate larger oligosaccharides clearly a variety of these will be generated which, like CS/DS oligosaccharides, must be subjected to SEC to separate them into differing sizes. These can then be further examined or the individual oligosaccharides isolated.

Gradient PAGE has been widely used for the analysis of the structure of heparin and HS. The actual resolving gel gradient will depend upon the nature of the oligosaccharides which are under investigation. A 20–30% gradient with a 5% stacking gel will, however, often be used for general purpose analysis; the gradient may extend up to 40% for large oligosaccharides.\(^{71,135}\) Samples should be loaded in 50% sucrose with bromophenol blue and phenol red as markers. Such gels provide greater resolution with oligosaccharides larger than tetrasaccharide.

Vives et al.\(^{136}\) have reported an HPLC method for sequence analysis of heparin and HS oligosaccharides. Radiolabeled (\(^3\)H) oligosaccharides derived by partial depolymerization were isolated and subjected to specific chemical and enzymatic depolymerization procedures. The oligosaccharides generated by these further treatments were identified by HPLC and the structure of the parent oligosaccharide deduced. In principle this method can be used to sequence any of the GAGs.

8 SUPPLIERS

General laboratory reagents along with chromatographic and other materials are widely available. However, specialist carbohydrate materials, including enzymes and GAGs, may be sourced from several companies. A comprehensive list is available at the Glycoscience Network web site (http://www.vei.co.uk/tgn/).

9 INTERNET GLYCOSCIENCE RESOURCES

There is an increasing number of glycoscience resources accessible using the Internet. One is the Bionet.Glycoscience newsgroup (http://tantalum-e2.hgmp.mrc.ac.uk/hypermail/Glycosci/). Any newsreader will allow you to access this resource and many popular web browsers have a newsreader built in. The Glycoscience Network (http://www.vei.co.uk/tgn/) is a gateway to the most useful glycoscience resources available.

ACKNOWLEDGMENTS

The Arthritis Research Campaign is thanked for support and Tom Huckerby, Ian Nieduszynski, Gavin Brown and Haydn Morris are thanked for helpful comments and critical reading of the manuscript.

This article gives a short historical review of the Chemical Weapons Convention (CWC), discusses the tasks of the Organisation for the Prohibition of Chemical Weapons (OPCW) related to chemical analysis, and lists the chemicals scheduled in the CWC. The Recommended Operating Procedures (ROPs) proposed originally by Finland and, subsequently, developed further in international cooperation, as well as the Standard Operating Procedures (SOPs) of the OPCW are briefly discussed. Strategy for analysis of CWC-related chemicals in an off-site laboratory is presented. The international interlaboratory comparison (round-robin) and proficiency tests are discussed.

1 INTRODUCTION

The section Chemical Weapons Chemicals Analysis consists of articles on sample preparation and analytical methods that have been used for analysis of chemicals related to the CWC in laboratories worldwide in the international interlaboratory comparison (round-robin) and proficiency tests. The analytical techniques are mass spectrometry (MS) (see Gas Chromatography/Mass Spectrometry in Analysis of Chemicals Related to the Chemical Weapons Convention; Gas Chromatography/Mass Spectrometry in On-site Analysis of Chemicals Related to the Chemical Weapons Convention; Liquid Chromatography/Mass Spectrometry in Analysis of Chemicals Related to the Chemical Weapons Convention), nuclear magnetic resonance (NMR) spectroscopy (see Nuclear Magnetic Resonance Spectroscopy in Analysis of Chemicals Related to the Chemical Weapons Convention), Fourier transform infrared spectroscopy (FTIRS) (see Fourier Transform Infrared in On-site and Off-site Analysis of Chemicals Related to the Chemical Weapons Convention), gas chromatography (GC) (see Gas Chromatography in Screening of Chemicals Related to the Chemical Weapons Convention), and capillary electrophoresis (CE) (see Capillary Electrophoresis in Detection of Chemicals Related to the Chemical Weapons Convention). Sample preparation for on-site and off-site analysis is presented in a separate article (Sample Preparation for Analysis of Chemicals Related to the Chemical Weapons Convention). On-site methods for analysis of CWC-related chemicals using FTIRS (Fourier Transform Infrared in On-site and Off-site Analysis of Chemicals Related to the Chemical Weapons Convention) and gas chromatography/mass spectrometry (GC/MS) (Gas Chromatography/Mass Spectrometry in On-site Analysis of Chemicals Related to the Chemical Weapons Convention) are described, the former in the article on off-site analysis. Two articles deal with detection and screening of CWC-related chemicals on-site (Detection and Screening of Chemicals Related to the Chemical Weapons Convention; Sampling, Detection and Screening of Chemicals Related to the Chemical Weapons Convention), while one also discusses the sampling (Sampling, Detection and Screening of Chemicals Related to the Chemical Weapons Convention). Techniques for real time detection of chemical warfare (CW) agents in the battlefield are not discussed.

The methods included in this section provide the best off-site performance for unambiguous identification of CWC-related chemicals. The success of the off-site analysis techniques has been unequivocally confirmed in international proficiency tests. The identification in on-site analysis relies on GC/EIMS (electron ionization mass spectrometry).

This article gives a short historical review of the CWC, discusses the tasks of the OPCW related to chemical analysis, and lists the chemicals scheduled in the CWC. The ROPs proposed originally by Finland and, subsequently,
developed further in international cooperation, as well as the SOPs of the OPCW are briefly discussed. Strategy for analysis of CWC-related chemicals in an off-site laboratory is presented. The international interlaboratory comparison (round-robin) and proficiency tests are discussed.

2 THE CHEMICAL WEAPONS CONVENTION

2.1 History

After World War I an international convention was signed on June 17, 1925, for the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare (the Geneva Protocol of 1925). The Convention entered into force on February 8, 1928. This Convention, which prohibits the use, but not the possession, development, storage and production of chemical weapons, was not respected and was openly violated. However, it prevented the massive use of chemical weapons in World War II. Negotiations for a new, comprehensive convention started in Geneva in 1968. The Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on their Destruction (the CWC) was signed on January 13, 1993, and entered into force on 29 April, 1997.1

2.2 Obligations

By October 1999, 126 countries have ratified the Convention and a further 44 countries have signed it. Each State Party to the Convention undertakes never, under any circumstances, to use, develop, produce, otherwise acquire, stockpile, or retain chemical weapons, or transfer, directly or indirectly, chemical weapons to anyone. Further, each State Party undertakes to destroy chemical weapons it owns or possesses and undertakes to submit declarations as required by the CWC. The State Parties also recognize that the new convention reaffirms principles and objectives of and obligations assumed under the Geneva Protocol of 1925.

2.3 Organisation for the Prohibition of Chemical Weapons

The OPCW was established in The Hague, the Netherlands, to achieve the objectives and purposes of the CWC and to ensure the implementation of its provisions, including those for international verification of compliance with it, and to provide a forum for consultation and cooperation among State Parties. The Convention requires State Parties to declare activities concerning chemical weapons and relevant parts of their civilian chemical industry. Declarations of existing chemical weapons and chemical industry are to be confirmed through on-site inspection. It is the responsibility of the inspectors, inter alia, to verify the quantity and identity of chemicals and the types and number of munitions, devices, and other equipment. Where possible, samples should be analyzed on-site, but if necessary they can be transferred for analysis off-site at designated laboratories.

The Director-General of the Technical Secretariat of the OPCW is to establish a stringent regime governing the collection, handling, transport, and analysis of samples, to certify the laboratories designated to perform different types of analysis, to oversee the standardization of equipment and procedures at these designated laboratories and the mobile analytical equipment and procedures, and to monitor quality control (QC) and overall standards in relation to the certification of the designated laboratories, mobile equipment and procedures. Selection will be made among the designated laboratories to perform analytical or other functions in relation to specific investigations.

In November 1998, the Director-General designated laboratories from seven countries (one from each country): China, Finland, the Netherlands, South Korea, Sweden, Switzerland, and the US. In June 1999, five other laboratories were designated (one from each country): Czech Republic, France, Germany, Poland, and the UK. In order to maintain or obtain designation, a laboratory has to participate annually in one OPCW proficiency test and perform successfully (see section 3.4). Another OPCW requirement for designation is national accreditation of the laboratory.

2.4 Definition of Chemical Weapons

Chemical weapons are defined as: (a) toxic chemicals and their precursors, except where intended for purposes not prohibited under the CWC, as long as the types and quantities are consistent with such purposes; (b) munitions and devices, specifically designed to cause death or other harm through the toxic properties of those toxic chemicals specified in (a), which would be released as a result of the employment of such munitions and devices; (c) any equipment specifically designed for use directly in connection with the employment of munitions and devices specified in (b).1 A toxic chemical means any chemical which through its chemical action on life processes can cause death, temporary incapacitation, or permanent harm to humans or animals. This general-purpose criterion was included to protect the CWC from circumvention. CW agent is a synonym for a chemical that acts as a chemical weapon.

2.5 Schedules of Chemicals

The toxic chemicals and their precursors that have been identified for the application of verification measures are listed in Schedules 1–3 (Table 1) contained in the

a Subject to special thresholds for declaration and verification.

CAS, Chemical Abstracts Service.

Annex on Chemicals of the CWC. Schedule 1 includes chemicals developed, produced, stockpiled, or used as a chemical weapon as defined above, and chemicals structurally close to them. Schedule 2 lists three toxic chemicals not included in Schedule 1 and degradation products and precursors of these toxic chemicals as well as of those of Schedule 1. Schedule 3 lists four toxic chemicals and precursors not listed in the other Schedules. Altogether tens of thousands of chemicals are included in the Schedules.

The Schedules contain mainly organic chemicals with different chemical and physical properties, being neutral chemicals, acids, bases, volatiles, and nonvolatiles, where phosphorus, fluorine, sulfur, chlorine, nitrogen, and oxygen occur frequently. Riot control agents are not included in the Schedules, but their use as a method of warfare is prohibited in the General Obligations of the CWC.

3 DETECTION AND VERIFICATION OF CHEMICAL WEAPONS

3.1 Recommended Operating Procedures

After more than 10 years of methods development for the identification of CW agents and their precursors and...
degradation products,\(^{(9,10)}\) the Finnish Research Project on the Verification of Chemical Disarmament (Finnish Institute for Verification of the Chemical Weapons Convention, VERIFIN) in 1988 and 1989 published SOPs for the Verification of Chemical Disarmament.\(^{(11)}\) In 1989, the first international interlaboratory comparison (round-robin) test for the verification of chemical disarmament was carried out.\(^{(2)}\) According to the proposal of the experts meeting, the SOPs were renamed ROPs. The first test and three subsequent tests\(^{(2)}\) were aimed at testing and developing the existing procedures, the ROPs. Through sustained international collaboration, the ROPs for Sampling and Analysis in the Verification of Chemical Disarmament were upgraded annually.\(^{(2,12)}\) In all these tests and in later proficiency tests the ROPs have been widely and successfully applied.

The ROPs\(^{(12)}\) give instructions for sampling, sample preparation, and instrumental analysis. Sampling will be the responsibility of the OPCW inspectors and sample preparation and subsequent analysis of the samples is carried out by the off-site laboratory in a case where further analysis is required. Rather than being the best choice for a single analyte or matrix type, ROPs provide an optimal approach for all in an unknown situation. The ROPs related to the sample preparation are listed in a separate article (Sample Preparation for Analysis of Chemicals Related to the Chemical Weapons Convention); the ROPs for the analysis techniques are the following:

- ROP for the Analysis of Treaty-related Compounds by Gas Chromatography;
- ROP for the Identification of Degradation Products of Treaty-related Compounds by Micro-liquid Chromatography with Flame Photometric Detection;
- ROP for the Identification of Methylphosphonic Acid and its Alkyl Derivatives by Ion Chromatography with Conductivity Detection;
- ROP for Capillary Zone Electrophoretic Analysis of the Alkylphosphonic Acids and Related Monoesters Using Indirect UV Detection;
- ROP for Identification of Treaty-related Compounds by Gas Chromatography/Mass Spectrometry;
- ROP for the Identification of Treaty-related Compounds and their Degradation Products by Liquid Chromatography/Thermospray/Mass Spectrometry;
- ROP for the Identification of Treaty-related Compounds and their Degradation Products by Liquid Chromatography/Atmospheric Pressure Chemical Ionization Mass Spectrometry;
- ROP for the Identification of Treaty-related Compounds by NMR Spectrometry;

### 3.2 Organisation for the Prohibition of Chemical Weapons Standard Operating Procedures

During the Preparatory Commission of the OPCW the Task Force on Analytical Issues discussed the analytical procedures required for on-site analysis. In June 1995, Finland, France, and the US presented proposals for on-site sample preparation methods. In October 1995, the French proposal was withdrawn and in February 1996, a collaboration program between Finland and the US was agreed. In January 1997, improved methods were accepted for training of the analyst inspectors of the OPCW. After this, the methods have been continuously developed and the results have been forwarded to the OPCW.

The OPCW has adopted the procedures and modified them. On 27 January, 1999 the OPCW established the first version and on 8 March, 1999 the second version of the SOP for On-site Analysis. This SOP sets a general OPCW strategy for chemical analysis on-site applicable to different inspection sites and types. The detailed procedures for protection, decontamination, collection, splitting, sample preparation, analysis, equipment, and chain-of-custody and documentation on-site are to be specified in

- SOP for the Donning and Doffing of Individual Protective Equipment;
- SOP for Set-up and Operation of the Contamination Control Station for the Decontamination of Personnel and Equipment;
- SOP for Preparation, Storage and Use of Decontamination Solutions I and II;
- SOP for Collecting and Splitting Samples under Toxic and Hazardous Conditions On-site;
- SOP for the Splitting of Samples On-site;
- SOP for Handling of Inspection Samples;
- SOP for the Chain-of-custody and Documentation During Inspection Period;
- SOP for the Collection of Wipe Samples On-site;
- SOP for the Collection of Liquid Samples On-site;
- SOP for the Collection of Solid Samples On-site;
- SOP for Preparation of Wipe Samples On-site for GC/MS Analysis;
- SOP for Preparation of Aqueous Samples On-Site for GC/MS Analysis;
- SOP for Preparation of Soil Samples On-site for GC/MS Analysis;
- SOP for Bruker EM 640S Portable GC/MS with AMDIS Data Analysis Software (Blinded Mode) for
The main analytical techniques in the SOP for On-site Analysis are GC/EIMS and FTIRS. The procedures for Fourier transform infrared (FTIR) are to be established in the future. GC/EIMS is the analytical technique used for chemical identification on-site. The off-site analyses performed by at least two different designated laboratories provide unambiguous results. In addition to the techniques mentioned here the inspection team may use, in certain conditions, the analytical techniques made available to it by the inspected State Party.

3.3 Analysis Strategy in Off-site Laboratory

In verification of presence or absence of chemicals related to the CWC (Table 1), the analysis of a specific sample in an off-site designated laboratory includes preparation of samples and their analysis by different chromatographic and spectrometric techniques. In general, the chromatographic techniques applying specific detectors are used in screening while the spectrometric techniques are used in a complementary manner to obtain unambiguous identification of Scheduled chemicals. According to the rules of the OPCW, identification is considered unambiguous if the results with two analytical, preferably spectrometric, techniques confirm the presence of the same chemical. Analyses are mostly qualitative (identification). Work is conducted according to the ROPs or other documented procedures of demonstrated performance. The analysis strategy employed at VERIFIN is described in the following (Figure 1). Laboratories worldwide may have different instrumentation and perhaps differing sample preparation procedures, which means that each laboratory actually requires its own analysis strategy.

3.3.1 Sample Preparation

After arrival, check-up, and coding, samples and blanks (if available) are divided into portions allowing multiple sample preparation procedures to meet the requirements of different analytical techniques and chemicals. QC samples may be prepared. By way of example, a blind sample containing only the solvents/reagents used in preparation of each type of sample is always prepared. One set of samples is prepared for the analysis techniques relying on GC separation. Samples from water and aqueous extracts can be prepared in a straightforward way for analysis by liquid chromatography/mass spectrometry (LC/MS) and CE. Samples for NMR are normally prepared so as to obtain 5- to 10-fold concentration. In the next stage, screening of the samples for the analytes is done by different analysis techniques.

3.3.2 Screening

The samples are always screened by GC. Results from screening by GC may be useful in analyses carried out by techniques relying on it. The screening is done with element (nitrogen, phosphorus, sulfur)-specific detectors (nitrogen–phosphorus detector (NPD) and flame photometric detector (FPD)) together with retention index (RI) monitoring. This is particularly advantageous, because almost all of the scheduled chemicals are then detectable without interference from hydrocarbons; the other chemicals not including phosphorus, nitrogen, and sulfur are screened using GC/EIMS by monitoring ions specific to them. GC/EIMS is also useful for screening of the family members of nerve agents (see Schedule 1.A.1–1.A.3) and their derivatized degradation products. Analogously, LC/MS is useful for screening of the degradation products, and there, no derivatization is required. Other screening techniques include $^{19}$F-NMR and/or $^{31}$P-$^[1]H$-NMR spectroscopy and CE. Screening by NMR can reveal phosphorus- and fluoride-containing chemicals, and screening by CE, for instance, presence of nonvolatile alkylphosphonic acids and their monoesters. One advantage of CE and LC/MS over GC techniques is the ability to separate and detect polar, nonvolatile analytes without sample pretreatment and derivatization. The boundary between screening and the identification is not always clear-cut.

3.3.3 Analysis, Data Evaluation, and Identification

Analysis for identification of known, volatile chemicals, which are fully resolved from the matrix, is carried out with GC/low-resolution MS: GC/EIMS provides a spectrum characteristic of the chemical, while GC/CIMS (chemical ionization mass spectrometry) provides molecular weight information. Problems caused by strong matrix interference are solved using GC/MS/MS (tandem mass spectrometry) or GC/HRMS (high-resolution mass spectrometry) in selective ion monitoring (SIM) mode. Polar and nonvolatile chemicals in aqueous solutions or extracts can be analyzed with LC/MS and LC/MS/MS by various ionization techniques (atmospheric pressure chemical ionization, APCl; electrospray ionization, ESI; or ionspray ionization, ISI). GC/FTIRS using cryodeposition offers pure and characteristic (solid-phase) spectra useful for identification. $^{1}$H-, $^{13}$C-$^[1]H$-, $^{19}$F-, $^{31}$P-$^[1]H$-, and $^{31}$P-NMR spectra are, as well, characteristic for a chemical, but in $^{1}$H-NMR,

sample background may cause problems of resonance overlapping.

In the case of MS, FTIRS, and NMR, the spectrum recorded from a sample is compared with library spectra, and upon fulfillment of certain criteria identification is obtained. In VERIFIN’s view, unambiguous identification of a chemical is obtained if at least two spectrometric techniques give consistent results. Identical identifications obtained by GC/EIMS and GC/CIMS are considered to constitute an unambiguous result.

If preliminary results indicate a Scheduled chemical which is not in the spectral libraries, its structure elucidation is carried out. The GC/EIMS, GC/CIMS, and LC/MS spectra are interpreted. Molecular weight and presence of heteroatoms like sulfur, chlorine, and phosphorus are determined. GC/MS/MS and LC/MS/MS assist in interpretation of the fragmentation of ions of interest. Elemental composition of the molecular and fragment ions can be determined with GC/HRMS. Interpretation of GC/FTIR spectrum provides information on functional groups, and the different types of one- and two-dimensional NMR spectra information on type and number of nuclei, and their location in the molecule, i.e. the molecular structure. A consistent result from all spectrometric techniques used is needed for unambiguous identification. The final confirmation is obtained when the suspected chemical is synthesized as a reference chemical, and the spectra recorded from the sample and the synthesized chemical are identical.

The analysis report must include all analytical data (chromatographic and spectrometric) supporting the identifications made, describe the sample preparation and analytical methods in detail (or make reference to ROPs, SOPs, or other procedures), and give information on the identified chemical (CAS registry number, structural formula, and International Union of Pure and Applied Chemistry or CWC name).

3.4 International Interlaboratory Comparison and Proficiency Tests

The first international interlaboratory comparison (round-robin) test for the verification of chemical disarmament took place in 1989 as a Finnish initiative. This test and three subsequent tests were coordinated by Finland. The Provisional Technical Secretariat (PTS) of the Preparatory Commission of the OPCW coordinated the first international OPCW/PTS interlaboratory comparison test in 1994 and two other tests in 1995. The tests of 1995 were also named “trial proficiency tests”. In 1996, a series of official proficiency tests was started and two tests were arranged. One test was arranged in 1997, two tests in 1998 and one test in 1999. In the future, the purpose is to arrange two proficiency tests annually, one in spring and one in autumn.

The aim of the OPCW proficiency tests is to establish and maintain a recognized and transparent methodology for the continued assessment of the technical competence of the participating laboratories. For this purpose, the Preparatory Commission of the OPCW established protocols to cover sample preparation and evaluation of the results of the OPCW proficiency tests: SOP for Preparation of Test Samples for OPCW/PTS Proficiency Tests and SOP for Evaluation of Results of OPCW Proficiency Tests. The scoring rules have been described in Criteria for Acceptable Performance of Laboratories in Proficiency Testing. In addition, the OPCW has made decisions on the criteria for the conduct of OPCW/PTS proficiency testing and for acceptable performance of laboratories in proficiency testing, and has given recommendations for the future on the basis of the Fourth and Fifth Official Tests.

This article describes the application of capillary electrophoresis (CE) to the analysis of compounds relevant to the Chemical Weapons Convention (CWC). CE is an analytical technique that employs narrow-bore, fused-silica capillaries to perform high-efficiency separations of analytes based on their mobilities in an electric field. In CE, analytes are dissolved in a buffer solution and placed in a capillary to which an electric field is applied. The analytes then migrate at a rate determined by their charge and size and are detected as they migrate past a detector. CE can analyze a broad range of compounds and is particularly applicable to the analysis of water-soluble degradation products of scheduled compounds under the CWC. Compounds typically analyzed by CE include the hydrolysis products of nerve agents such as the alkylphosphonates and hydrolytic or oxidative products of the sulfur mustards such as thiodiglycol. The alkylphosphonates require the use of indirect ultraviolet (UV) detection or other detection methods as they do not possess a suitable UV chromophore. Degradation products of the sulfur mustards have been analyzed by micellar electrokinetic chromatography (MEKC) and direct UV detection. The ability of CE to analyze anionic, cationic, zwitterionic, and neutral CWC-related compounds, whether they be chemical warfare (CW) degradation products or scheduled starting materials, without the requirement for elaborate sample processing or labeling procedures, is an important demonstration of the utility of CE for the analysis of CWC-related compounds. CE can be an important screening method for rapid sample processing and further analysis for unambiguous identification. The relative ease of analysis should also increase its utility in field and on-site analysis where minimizing the logistic burden is attractive.

1 INTRODUCTION

CE is an analytical technique that employs narrow-bore, fused-silica capillaries to perform high-efficiency separations of analytes based on their mobilities in an electric field. The separation efficiency, which may be greater than 1000000 theoretical plates, is superior to that of many other chromatographic methods and is an important reason for the rapid growth of this technique. In CE, analytes are dissolved in a buffer solution and placed in a capillary to which an electric field is applied. The analytes then migrate at a rate determined by their charge and size and are detected as they migrate past a detector. CE can analyze a broad range of compounds, has a simple instrument design which can be fully automated, and has very low volume requirements (nanoliter injection volumes are typical).

The Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and their Destruction, otherwise known as the CWC, is an international treaty which will potentially eliminate the worldwide threat of CW. CW agent degradation
products or impurities can provide an indication of CW agent use, act as tracers to follow synthetic routes, or identify sources of precursors. For instance, analysis of samples taken during an allegation of use investigation were found to contain mustard (H) as well as other longer chain sulfur vesicants.\(^\text{8}\) The identification of isopropyl methylphosphonic acid and methylphosphonic acid, decomposition products of the nerve agent isopropyl methylphosphonofluoridate (sarin (GB)), has also been reported in soil samples taken from bomb craters in Iraq years after the alleged attack.\(^\text{9}\) More recently, isopropyl methylphosphonate has been detected in the urine\(^\text{10}\) and serum\(^\text{11}\) of persons exposed to GB during a terrorist attack in Japan.\(^\text{12}\)

The degradation products of CW agents are often polar, water-soluble compounds. Thus analytical techniques which can directly analyze the target compounds without the need for derivatization are valuable for both on-site screening of samples and laboratory-based identification. CE is an important analytical method for the detection of these analytes because of the efficiency of separation, speed of analysis, and ease of operation. Degradation products of CW nerve agents are primary targets for analysis. However, these organophosphates are non-UV-absorbing and so are generally analyzed by indirect detection methods. Other compounds, such as the decomposition products of sulfur mustards, can be analyzed by direct UV detection but are non-ionizable and require the use of special CE experimental conditions. However, both classes of compounds have been readily analyzed, demonstrating the versatility of CE for the analysis of CWC-related compounds. The development of instruments for atmospheric pressure ionization mass spectrometry (MS) and the advent of commercial instruments for CE combined with electrospray ionization mass spectrometry (ESIMS) will greatly increase the importance of CE for the identification of CW agents and their degradation products.

2 CAPILLARY ELECTROPHORESIS

CE has been the subject of extensive reviews\(^\text{13–16}\) and there are several books and publications describing the technique.\(^\text{17,18}\) Key aspects of CE are discussed here to introduce CE and to review important fundamental issues for the analysis of CWC-related compounds. These issues can affect the quality of CE separations, detection of target compounds, and method development. Specialized CE methods, such as capillary gel electrophoresis (CGE), capillary isoelectric focusing (CIEF), capillary isothermal-chromatography (CITP), and capillary electrochromatography (CEC) are beyond the scope of this article.

2.1 Capillary Zone Electrophoresis

Capillary zone electrophoresis (CZE) has been used for the analysis of amino acids, peptides, ions, enantiomers, and many other ionic species. CZE is the simplest form of CE, employing a narrow-bore, bare fused-silica capillary (10–200 µm i.d., 370 µm o.d., polyimide coated) filled only with buffer. CZE achieves high-efficiency separations of both large and small molecules based on their mobilities in an electric field. The instrument design is fairly simple, consisting of two buffer reservoirs connected via a fused-silica capillary, a high-voltage power supply, and a detection system.\(^\text{19}\)

Surface silanol groups of the bare fused-silica capillaries are partly ionized (SiO\(^{\text{2+}}\)) in the presence of the electrophoretic medium, a run buffer in the pH range 2.5–10. This leads to the formation of a double layer of immobile cations tightly bound to the negative charges on the silica and a potential difference (zeta potential). Adjacent to this layer is a layer of weakly bound cations and their sphere of hydration. When a potential is applied across the capillary, these solvated cations migrate towards the cathode, resulting in a net flow of liquid through the capillary known as electroosmotic flow (EOF). The EOF is greater in magnitude than the mobility of the ions. Therefore, all analytes are swept in the same direction, regardless of charge. The zeta potential is also dependent on the ionic strength of the buffer. Increasing ionic strength decreases the zeta potential and thus the EOF. Selectivity in CZE is affected by the buffer pH and buffer additives (e.g. surfactants, EOF modifiers, or chiral selectors).

Since the EOF can be significantly greater than the electrophoretic mobilities of the individual ions in the sample, both anions and cations can be separated in the same run. Cations with the smallest mass-to-charge ratio are the fastest migrating species followed by cations with higher mass to charge ratios, then neutral species, and lastly anions. Anions migrate because they are swept to the cathode by the EOF. Control of the EOF is thus an important experimental consideration in method development and reproducibility of the analysis.\(^\text{20–22}\) The conditions used during a CE separation can greatly affect the selectivity of the separation and so the run buffer selection and composition are extremely important to the success of any CE separation.

2.2 Electrophoretic Mobility

Identification of an analyte can be made on the basis of migration time or relative migration times, or by measurement of an analyte’s electrophoretic mobility. Measurement of the electrophoretic mobility can compensate for variability in the migration time due to unstable electric
field, changes in buffer capacity or composition, temperature fluctuations, and changes to the capillary surface conditions.\textsuperscript{23–25} The apparent electrophoretic mobility (\(\mu_{\text{app}}\)) is characteristic for a given species at a certain pH. The apparent mobility results from the sum of the true electrophoretic mobility of the ion due to the electric field (\(\mu_e\)) and the mobility due to the EOF (\(\mu_{\text{EOF}}\)).

Apparent mobility (\(\mu_{\text{app}}\)) can be calculated from the experimental data using Equation (1):

\[
\mu_{\text{app}} = \frac{v}{E} = \frac{L_d L_t}{t} \frac{1}{V}
\]  

where \(v\) is the velocity of an ion, \(E\) is the applied field strength (V cm\(^{-1}\)), \(L_d\) is the length from capillary to detector, \(L_t\) is the total length of capillary, \(t\) is the migration time, and \(V\) is the applied voltage.

In order to determine the electrophoretic mobility due solely to the attraction to the cathode (\(\mu_e\)), a neutral EOF marker must be used to determine the mobility due to the EOF (\(\mu_{\text{EOF}}\)). Equation (2):

\[
\mu_e = \mu_{\text{app}} - \mu_{\text{EOF}}
\]

Acetone, methanol, benzyl alcohol, and mesityl oxide can be used as EOF markers.

### 2.3 Capillary Electrophoresis Separation, Efficiency, and Resolution

Separations performed by CE are directly dependent on differences in the analyte mobilities and inversely dependent on the band broadening of the analytes as they migrate through the column. An important advantage of CE is that owing to EOF, the flow profile has a plug-shape as opposed to the parabolic flow profile of high-performance liquid chromatography (HPLC). This plug-shaped flow profile increases the resolution because the EOF is uniform throughout the capillary, resulting in much less band broadening due to frictional forces along the walls and pressure gradients across the column as is seen with pressure-driven systems.

Any factors contributing to band broadening will decrease the efficiency and resolution of the separation. A major source of band broadening in CE separations is the heat generated by the passage of electrical current through the fused-silica capillary. This is called Joule heat. The increase in temperature within the CE column depends on the power generated (power = voltage \(\times\) current) and is determined by the capillary dimensions, conductivity of the buffer, and applied voltage. Excessive heat causes a nonuniform temperature gradient which changes the buffer viscosity across the capillary diameter. This results in different ion mobilities across the column, leading to band broadening. Thus an inherent advantage of performing CE in narrow-bore capillaries as compared with traditional electrophoresis is the rapid heat dissipation and reduction in the effects of heating. The efficiency expressed in theoretical plates (\(N\)) is given by Equation (3):

\[
N = \frac{\mu_e E L_t}{D^2}
\]

where \(\mu_e\) is electrophoretic mobility, \(E\) is electric field, \(L_t\) is total length of the capillary, and \(D\) is the diffusion coefficient.\textsuperscript{26}

It is evident from Equation (3) that the efficiency can be increased by increasing the electric field. However, this also results in increased Joule heating. Therefore, a balance between these two parameters must be achieved. Experimental parameters which can be optimized to limit Joule heating include decreasing the electric field (reducing the applied voltage), reducing the capillary internal diameter, decreasing the buffer ionic strength or concentration, and active temperature control.\textsuperscript{27}

### 2.4 Limits of Detection

The limits of detection (LODs) of CE are comparable to those of other chromatographic methods. CE, because of its very low volume requirements, has very good mass sensitivity. Typical injection volumes are in the range 1–50 nL. Thus the often reported impressive picomole to femtomole mass detection limits are actually only in the low milligrams to high micrograms per liter (parts per million to parts per billion) range. Such concentrations are easily achieved by HPLC. The concentration limit of detection (CLOD), typically in the micromolar range, is higher than for HPLC where typical injection volumes of 1–10 \(\mu\)L allow for higher column loading.

Approaches to improvements in sensitivity include both precolumn and on-column sample concentration, derivatization with laser-induced fluorescence (LIF), and modification to the detection system.\textsuperscript{28} On-column methods offer the advantage for trace analysis of minimizing the sample handling and possible loss of analyte. Three approaches are commonly used for sample concentration: sample stacking, sample focusing, and isotachophoresis. More recently, the development of on-line sample extraction devices such as solid-phase preconcentration phase CE has permitted injection volumes as high as 100 \(\mu\)L.\textsuperscript{29}

### 3 Chemical Weapons Convention and Related Compounds

#### 3.1 Scheduled Chemicals

The CWC contains schedules of chemicals with specific verification and reporting requirements. The ‘‘Annex on
1.A. (1) Decomposition of O-alkyl methylphosphonofluoridates (GB, GD, GF)

\[ \text{R'}OPF \xrightarrow{\text{Fast}} \text{HO}O\text{POH} + \text{CH}_3 \]

1.A. (3) Decomposition of O-alkyl S-2-dialkyaminaoethyl alkylphosphonothiolates (e.g. VX)

\[ \text{R'}OP-SCH}_2\text{CH}_2\text{NR}'' \xrightarrow{\text{H}_2\text{O}} \text{HO}O\text{PSCH}_2\text{CH}_2\text{NR}'' + \text{R'}OP\text{OH} + \text{HSCH}_2\text{CH}_2\text{NR}_2 \]

1.A. (4) Decomposition of sulfur mustards

\[ \text{Cl}_2\text{S Cl} \xrightarrow{\text{H}_2\text{O}} \text{HO}O\text{S OH} + \text{Cl}_2\text{S Cl} \]

**Figure 1** Major degradation pathways of Schedule 1 CW agents. GD, soman; GF, cyclohexyl sarin.

Chemicals” describes the guidelines for inclusion of a chemical on each of the three schedules. The Annex also lists specific classes, toxic chemicals, and their precursors for which specific reporting and verification measures are applied under the Verification Annex of the CWC. Each schedule is divided into toxic chemicals and precursors. Schedule 1.A lists those chemicals which pose a high risk to the CWC and which have been developed, produced, stockpiled, or used as chemical weapons. In addition to the toxic chemicals, certain chemicals and classes of chemicals are also scheduled because they can be used as immediate precursors for the production of Schedule 1 chemicals. These chemicals are seen to have little or no use for purposes not prohibited by the CWC.

The principal classes and chemicals under Schedule 1 of the CWC include classical CW agents such as the O-alkyl alkylphosphonofluoridate nerve agents (e.g. GB, CAS 107-44-8), the N,N-dialkyphosphoramidocyanidates (e.g. tabun (GA), CAS 77-81-6), and the S-dialkyaminaoethyl alkylphosphonothiolates (e.g. O-ethyl S-2-diisopropylaminoethyl-methyl phosphonothiolate (VX), CAS 50782-69-9). Three vesicant (blistar agent) classes are scheduled: the sulfur mustards (e.g. mustard gas (HD), CAS 505-60-2), the lewisites (e.g. Lewisite 1, CAS 541-25-3); and the nitrogen mustards (e.g. ethyl nitrogen mustard (HN-1), CAS 538-07-8). Two special compounds are also included in the schedule for which CE analysis has been applied in particular, the paralytic shellfish toxin saxitoxin (STX, CAS 35523-89-8) and I.A.(8) the glycoprotein ricin (CAS 9009-86-3).

### 3.2 Degradation Products of Chemical Warfare Agents

The degradation and decontamination chemistry of CW agents has been reviewed previously.\(^{30,31}\) Degradation can occur from natural weathering, as a result of decontamination, or by deliberate attempts to destroy or neutralize CW agents as might occur in a clandestine production facility. Figure 1 shows the major degradation pathways of Schedule 1 chemicals which lead to water-soluble products which can be analyzed by CE. O-Alkyl alkylphosphonofluoridate nerve agents such as GB undergo a two-step degradation in water or under alkaline conditions. The initial degradation product is isopropyl methylphosphonate followed by a slower hydrolysis to methylphosphonic acid. Hydrolysis of S-dialkyaminaoethyl alkylphosphonothiolates such as VX leads to the formation of S-2-diisopropylaminoethyl methyl phosphonothiolate and ethyl methylphosphonate. Sulfur mustards can undergo both hydrolytic and oxidative decomposition. The primary hydrolysis product is thiodiglycol. Thiodiglycol sulfoxide and sulfone can arise directly from the hydrolysis of the oxidation products of mustard or the oxidation of thiodiglycol.

### 4 CAPILLARY ELECTROPHORETIC ANALYSIS OF CHEMICAL WEAPONS CONVENTION RELATED COMPOUNDS

#### 4.1 Chromatographic Analysis of Chemical Weapons Convention Related Compounds

Unfortunately, as organophosphorus nerve agents readily undergo hydrolysis, identification of the intact CW agent is not always possible and the detection or identification of degradation products including alkyl methylphosphonic acids and methylphosphonic acid is more likely. Chromatographic methods, including ion chromatography (IC),\(^{33,34}\) have been developed
for the tentative identification of these hydrolysis products. However, unambiguous identification requires the acquisition of spectrometric data from two different spectrometric techniques. Proton and phosphorus nuclear magnetic resonance (NMR) spectroscopy have been applied to the trace analysis of CW agents and related compounds in rubber, paint, and soil. MS and NMR has been used for the unambiguous identification of novel CW decomposition products relevant to verification.

Hyphenated MS techniques such as with gas chromatography (GC), HPLC, or CE are preferred for multi-component environmental samples. Nerve agent hydrolysis products, including a number of alkyl methylphosphonic acids and methylphosphonic acid, have been analyzed by gas chromatography/mass spectrometry (GC/MS) (see below). The polarity of these products require derivatization of the hydroxyl groups prior to GC separation and a number of derivatizing agents have been employed to enhance volatility. GC/MS methods have been reported for alkyl methylphosphonic acids, methylphosphonic acid, and related degradation compounds following tert-butylidemethysilylation, methylation with trimethylphenylammonium hydroxide, trimethylsilylation, and derivatization with pentafluorobenzyl bromide. Derivatization methods allow the analyst to use the same GC/MS instrumentation as used for the CW agent analysis but suffer from the need to modify the intact scheduled compound prior to identification.

HPLC coupled with MS offers the opportunity to analyze the polar, ionic organophosphorus nerve agent hydrolysis products without the need for derivatization. Thermospray MS and tandem mass spectrometry (MS/MS) have been demonstrated for the identification of organophosphorus nerve agents and their hydrolysis products. Since the mid-1990s, this ionization technique has been largely superseded by atmospheric pressure ionization methods, including electrospray (ES) and ionspray (IS), both of which have been applied to the analysis of organophosphorus nerve agents hydrolysis products. CE offers an important alternative chromatographic technique for the separation of target compounds prior to MS analysis.

4.2 Capillary Electrophoresis Analysis of Organophosphates

The primary degradation products of the alkylphosphonofluoridate CW agents [Schedule 1.A(1)], the alkyl alklyphosphonates, do not have a UV chromophore or fluorophore suitable for direct detection. The most common detection mode for these compounds is indirect UV detection using a high UV-absorbing background electrolyte (BGE). Analysis of low-molecular-weight organic ions, such as methylphosphonic acid, has also been described as capillary ion electrophoresis (CIE). In these CIE methods EOF modifiers are used to reverse the EOF. Under these conditions, the anionic organophosphates comigrate with the EOF, a condition referred to as co-EOF. The EOF is modified using run buffer additives or by modifying the capillary surface. Table 1 lists the organophosphate compounds analyzed by CE, including all modes of detection.

4.2.1 Indirect Ultraviolet Detection

In indirect detection, the analyte displaces a UV-absorbing BGE in the separation buffer. Detection is due to a decrease in the UV signal as the analyte, which has displaced the BGE, passes through the detector window.

Detection is in effect done in a high-noise system owing to the strongly absorbing BGE. Thus detection limits are generally poorer than for direct UV methods. As shown in Equation (4):

\[ \text{CLOD} = \frac{C_{\text{BGE}}}{KDr} \]  

the CLOD is directly related to the concentration of the BGE \( (C_{\text{BGE}}) \) and inversely proportional to the displacement ratio \( (R) \) of the analyte and BGE and the dynamic reserve \( (Dr) \). The dynamic reserve is the ability of the detector to detect a small change in signal on top of a large signal. Optimization of detection limits involves careful selection of BGE and the lowest \( C_{\text{BGE}} \) should be employed. The detector must provide a large dynamic reserve and the displacement ratio should approach unity. The BGE should also have an electrophoretic mobility close to that of the analytes to maximize sensitivity and minimize dispersion effects that can arise from the electrophoretic mobility differences between the analyte and the BGE.

CZE with indirect UV detection at 254 nm was first used for the detection of a series of alklyphosphonic acids. Four BGEs were investigated, benzoic acid, phthalic acid, sorbic acid, and phenolphosphonic acid. Phenolphosphonic acid, which has a mobility close to that of the analyzed compounds, was shown to be the most suitable BGE. The influence of several parameters, such as the concentration of the BGE and the borate buffer on both sensitivity and efficiency, was investigated. An increase in the borate concentration produced an improvement of the signal-to-noise ratio \( (S/N) \) while the sensitivity decreased with increasing concentration of the phenolphosphonic acid. At pH 6, 200 mM sodium borate buffer containing 10 mM phenolphosphonic acid was selected and the separation of MPA, EPA, PPA, and BPA was demonstrated. The reproducibility of the \( \mu_e \) for

</table>

MPA was 1.65% (relative standard deviation) and the LOD was <10μM (0.21 pmol injected).

Sorbic acid has also been shown to be a suitable BGE for the analysis of the alkylphosphonic acids and their monoester derivatives. A run buffer consisting of 5 mM sorbic acid and 0.1 M decamethonium bromide, adjusted to pH 6, was used to separate a mixture of eight alkyl alkylphosphonates. The use of an EOF modifier, decamethonium bromide, reduced the EOF at pH 6 and gave complete separation of the alkylphosphonic acids and their monoester derivatives (e.g. MPA and IMPA) in <15 min (Figure 2).

To reduce run times while maintaining high peak efficiencies, the capillary can be dynamically coated with a cationic polymer to reverse the EOF. In the procedure the column is flushed with a polymer solution prior to each analysis. This approach has been demonstrated with a 0.2% aqueous solution of polybren. Sorbic acid was used as the BGE and hydroxylamine was added to improve the buffer capacity of the run buffer. Using an electrolyte composed of 5 mM sorbate anion (pH 6) and 1.6 mM hydroxylamine allowed the separation of alkylphosphonic acid monoesters in <6 min. Chromate

![Figure 2](image-url)
has also been used as a BGE in the presence of a proprietary EOF modifier for the separation of MPA, EMPA, IMPA, and PMPA.\(^{54}\)

4.2.2 Direct Ultraviolet Detection

The direct UV detection of alkylphosphonic acids through the formation of sodium borate complexes has been reported.\(^{55}\) The buffer system consisted of 10 mM sodium tetraborate with complexation occurring in solution at pH 7 and higher. The reported detection limits were of the order of nanograms. The UV, Infrared (IR), NMR, and mass spectra of various borate–phosphonic acid esters were also reported.

4.2.3 Flame Photometric Detection

The separation performance and sensitivity of a CE system coupled on-line with a flame photometric detector (FPD), originally developed for GC, have been reported for the detection of alkylphosphonic acids.\(^{56}\) The liquid junction used to decouple the electric field from the FPD showed a negligible influence on the performance of the system as compared with online UV detection. Use of an on-column sample stacking pre-concentration technique allowed for injection of 900 nL. With the large injection, the detection limits for the alkylphosphonic acids in water were 0.1–0.5 µg mL\(^{-1}\).

4.2.4 Mass Spectrometric Detection

MS is the only technique which to date has been coupled with CE to provide the structural information required for unambiguous identification of CW degradation products. Capillary zone electrophoresis/ionspray mass spectrometry (CZE/ISMS) combines the high separation efficiency of CE and the high sensitivity of MS for the analysis of these polar degradation products. CZE/ISMS, in the negative-ion mode, was applied to the identification of five organophosphonic acids which are the primary hydrolysis products of nerve agents.\(^{57}\) The spectra of EMPA, IMPA, and PMPA exhibited very abundant \([M - H]^−\) ions of \(m/z\) 123, 137, and 179, respectively. The fragmentation was minimal and common fragmentation ions at \(m/z\) 95 and 79 were observed due to the loss of the alkyl and alkoxy groups, respectively. Sensitivity in the range 10–30 pg (5 ng µL\(^{-1}\)) was achieved using selected ion monitoring (SIM).

4.3 Sulfur-containing Compounds

4.3.1 Micellar Electrokinetic Chromatography

MEKC is a combination of electrophoresis and chromatography.\(^{58,59}\) The main advantage of MEKC is that it can be used for the separation of both neutral and charged solutes. This is done by adding a surfactant such as sodium dodecylsulfate (SDS) at concentrations above the critical micelle concentration to the running buffer to form micelles. Neutral species partition in and out of the micelle. Since the micelles are charged, this partitioning imparts a mobility to the neutral species. The more hydrophobic the analyte, the more it is retained within the micelle and the more it is affected by the charge of the micelle. Since MEKC can be used for both charged and uncharged species, its applications include analyses of amino acids, nucleotides, vitamins, pharmaceuticals, aromatic hydrocarbons, and explosive constituents.

The sulfur-containing, neutral degradation products of mustard and related vesicants can be analyzed by direct UV detection using MEKC. MEKC has been used for the analysis of thiodiglycol (TDG), 2,2'-sulfinyldiethanol (TDGO), 1,4-dithiane, 1,4-thioxane, O-isobutyl methylphosphonothioic acid (IBMPSA) and O-ethyl methylphosphonothioic acid (EMPSA). These were separated in under 10 min with a run buffer of 10 mM borate and 100 mM SDS at pH 9 (Figure 3).\(^{60,61}\) Detection limits range from 1 to 10 µg mL\(^{-1}\). Sulfur-containing compounds related to the decomposition of sulfur mustard and other materials analyzed by CE with direct UV detection are listed in Table 2.

**Figure 3** MEKC of six sulfur-containing compounds related to the degradation of mustard and \(O\)-alkyl alkylphosphonothioates (solute concentration 50 mg L\(^{-1}\)): TDGO (1), TDG (2), thioxane (3), IBMPSA (4), dithiane (5), and EMPSA (6). MEKC analysis conditions: 57 cm L\(_{t}\) (50 cm L\(_{d}\)) x 75 µm i.d.; \(V = 25\) kV; 10 mM borate, 100 mM SDS, pH 9; direct UV detection at 200 nm; 3 s hydrodynamic injection. (Reprinted from J.-P. Mercier, Ph. Morin, M. Dreux, A. Tambute, *J. Chromatogr. A.*, 741, 279–285 (1996), Copyright 1996, with permission from Elsevier Science.)
4.4 Toxins

4.4.1 Saxitoxin

STX, Schedule I.A.(7), is a potent neurotoxin which can cause paralytic shellfish poisoning (PSP). STX is produced by certain strains of dinoflagellates, which leads to the contamination of commercial shellfish and causes severe outbreaks of seafood poisoning. The public health problems caused by these outbreaks have led to significant interest in the development of analytical methods for the determination of STX in environmental and biological samples. STX is also one of several closely related compounds and separation and so unambiguous identification of the target compound is a significant analytical requirement for its analysis.

STX is one of the only CWC-related compounds which has been analyzed by CZE with LIF detection. Peptides and proteins containing lysine residues or natural products which contain primary amino groups (NH₂) can be derivatized with a number of fluorescent labeling reagents. LIF is an extremely sensitive detection method and can provide CLODs in the 10⁻¹¹–10⁻¹³ M range. STX has been labeled with fluorescamine, o-phthaldialdehyde (OPA) and dansyl chloride and detection limits as low as 0.1 amol were reported for the OPA derivative of STX. However, the precolumn labeling methods required micromolar concentrations of analyte, limiting the utility in trace analysis. Labeling, separation, and analysis of STX were best accomplished using the fluorescamine derivative, which produces ionic derivatives that can be separated from other fluorescently labeled marine toxins such as tetrodotoxin and microcystin.

CE analysis with direct UV absorbance detection at 200 nm has been described for the separation and detection of underivatized toxins, including STX, associated with PSP. Confirmation of the electrophoretic peaks was made by capillary electrophoresis/electrospray ionization mass spectrometry (CE/ESIMS). STX and neosaxitoxin (NEO) were separated using 20 mM sodium citrate buffer (pH 2.1) with a mass detection limit of 15 pg (5 µM) for STX. This method was able to detect STX and NEO algal and mollusc extracts. Another reported UV method uses 208 nm and a 0.06 M sodium borate buffer for the analysis of STX in molluscs.

The application of on-column sample preconcentration CITP and a discontinuous buffer system prior to CE separation has been investigated for the analysis of PSP toxins. Using a linear polyacrylamide-coated capillary to eliminate EOF during the CITP step, 35 mM morpholine (pH 5) as the leading electrolyte and 10 mM formic acid as the terminating electrolyte, the improvement of the CLOD is at least two orders of magnitude over that obtainable using the conventional CZE format. Analyses performed using SIM ESIMS provided a CLOD of 16 nM for STX. This preconcentration technique was compatible with ESIMS and permitted the analysis of biological extracts containing PSP toxin levels as low as...
100 nM. In situations where higher levels of selectivity are required for unambiguous identification of individual PSP toxins, CITP or CZE with MS/MS can be used. Further improvements in sample focusing prior to CE separation can be obtained using high-ionic-strength buffers and on-column sample stacking.\(^{(68)}\)

4.4.2 Ricin

CE has found particular application in the analysis of peptides\(^{(69,70)}\) and proteins.\(^{(71,72)}\) The resolution and ease of operation combined with the various CE modes such as CGE have led to a tremendous number of applications for CE analysis of amino acids, peptides, and proteins. Proteins are readily analyzed by direct UV detection at 200 nm. CE analysis of proteins can present additional challenges such as sample microheterogeneity due to variations in carbohydrate structure, impurities from the isolation or preparation of the protein sample, or surface adhesion to the capillary walls. This can result in multiple peaks or significant peak broadening, peak tailing, and even irreversible loss of protein.

Ricin is a heterodimeric glycoprotein (MW = 66 000) produced by the castor bean plant *Ricinus communis* with the two protein subunits linked by a single disulfide bond. Conditions for the analysis of ricin with CE, using uncoated and coated columns, and the influence of buffer systems (run buffer composition, pH, ionic strength, and additives) have been investigated. Uncoated columns used with either zwitterionic salts or putrescine gave the best results.\(^{(73,74)}\) Multiple peaks were resolved with these conditions. Analysis using a bare fused-silica column with a 0.03 M sodium borate run buffer gave a single, broad, tailing peak which could be due to protein–column interactions, additional components, or both. The use of 0.03 M putrescine (1,4-diaminobutane) in 0.02 M K₂SO₄ buffer (pH 7) gave better resolution and peak shape and multiple peaks were resolved, indicating possible impurities or microheterogeneity in the ricin sample.

5 APPLICATIONS

5.1 Environmental Analysis

The development of CE analytical methods for CW-related compounds has been directed primarily towards the analysis of these compounds in environmental matrices such as soil and water. These methods have been used in the analysis of samples distributed as part of interlaboratory comparisons exercises, the so-called Finnish Round Robin Exercises\(^{(38)}\) and more recently the Organization for the Prohibition of Chemical Weapons (OPCW) Laboratory Proficiency Testing.\(^{(75)}\)

The use of CE with indirect UV detection in environmental samples leads to matrix effects from inorganic ions that comigrate. Surface or groundwater samples can contain carbonate levels that interfere with alkylphosphonate analysis. Ion-exchange cartridges such as the Milli-Trap H⁺ (Waters) can be used to reduce carbonate levels and Ag⁺ resins can be used to remove chloride ions.\(^{(59)}\) Using decamethonium bromide to reduce the EOF, CEPA- and EPA-spiked soil samples, extracted with water, could be analyzed without significant interferences.\(^{(57)}\) However, differences in the migration times were noted owing to matrix effects in the soil extracts and required the use of a standard to achieve quantitative results. Environmental water samples, spiked with standard mustard degradation products, have been analyzed by MEKC with direct UV detection with no apparent interferences or requirement for sample pretreatment.\(^{(66)}\)

As part of an Interlaboratory Proficiency Test, CE with FPD was used to screen water samples and aqueous extracts of soil, rubber, and paint for spiked alkylphosphonic acids.\(^{(61)}\) The water sample had been spiked with PPA at a level of 8 µg mL⁻¹ and one soil sample was spiked with CEPA and EPA at 15 and 8 µg g⁻¹, respectively. Although the recovery efficiency was only approximately 20%, CEPA and EPA could still be detected using longer injection volumes and higher on-column concentrations. Subsequent NMR and tert-butylidimethylsilyl derivatization and GC/MS analysis confirmed the identity of the phosphorus-containing compounds in the extract.

Reversal of EOF was used in the analysis of samples in the second and third OPCW Laboratory Proficiency Tests.\(^{(76)}\) The cationic surfactants didodecyldimethylammonium hydroxide and cetyltrimethylammonium hydroxide were used to reverse the EOF and remove interferences from common anions and give complete and rapid separation of alkylphosphonic acids. EPA and PEPA were detected in water samples as part of the second OPCW test and PPA and EHMPA were detected in the water samples as part of the third OPCW test. Identification of spiked compounds was first made on the basis of mobility data and confirmed by MS. The method was applied to aqueous leachates of soil, wipes of surfaces, and vegetation sampled from a field site known to have been exposed to nerve agents and subsequently remediated. MPA, IMPA, and PMPA were detected in these samples, indicating that the method can be useful for environmental monitoring.

5.2 Quality Assurance

Under the terms of the CWC, the Director General of the OPCW shall establish stringent regimes governing the collection, handling, transport, and analysis of
samples. The Director General shall also certify laboratories designated for the analysis of samples, oversee standardization of procedures, and monitor quality control standards at certified laboratories. To be certified as a “Designated Laboratory” by the OPCW under the terms of the CWC, a laboratory must have established an internationally recognized quality assurance system, obtained accreditation by an internationally recognized accreditation body for which they are seeking accreditation, and regularly participate and perform successfully interlaboratory proficiency tests. A requirement for accreditation of testing laboratories under such standards as the “General Criteria for the Operation of Testing Laboratories”, European Standard 45 001: European Standards Institution, Brussels EN 45 001, is that the laboratory follow written standard operating procedures and implement a quality assurance/quality control program.

In addition to demonstrating the role of analytical methods in verification of the CWC, the round-robin methods have led to the publication of recommended operating procedures which can be used for the analysis of the target compounds. The published method of Pianetti et al. has been put forward as a recommended operating procedure for the analysis of the alkylphosphonates. Other representative methods for the analysis of various CWC-related compounds which could form the basis of a standard or recommended operating procedure in a designated laboratory are summarized in Table 3.

A validated quantitative analysis for CW degradation products has been developed. The specificity, linearity, precision, and accuracy were examined for the analysis of IMPA and PMPA using two buffer systems and detection methods. The method gave inter- and intra-day reproducibility of 1–3% (relative standard deviation). The method requires little sample preparation except for dilution with deionized water and is not prone to interference from carbonate or fluoride ions.

$^a$ BGE.

6 CONCLUSION

The ability of CE to analyze anionic, cationic, zwitterionic, and neutral CWC-related compounds, whether they be CW degradation products or scheduled starting materials, without the requirement for elaborate sample processing or labeling procedures is an important demonstration of the utility of CE for the analysis of CWC-related compounds. CE can be an important screening method for rapid sample processing and further analysis for unambiguous identification. The relative ease of analysis should also increase its utility in field and on-site analysis where minimizing the logistic burden is attractive. The increased use of MS coupled techniques and the advent of CE coupled with NMR will also serve to establish CE as an important method for the unambiguous identification of CWC compounds.

DETECTION AND SCREENING OF CHEMICALS RELATED TO THE CHEMICAL WEAPONS CONVENTION

Detection and Screening of Chemicals Related to the Chemical Weapons Convention

Maarten S. Nieuwenhuizen
TNO Prins Maurits Laboratory, Rijswijk, The Netherlands

1 Introduction

Verification procedures dealing with chemical warfare agents (CWAs) and other chemicals scheduled in the text of the CWC(1) may consist of:

1. Location of the area of interest for inspection scenarios dealing with CWA storage, production and destruction facilities and industrial facilities and old and abandoned chemical weapons sites, as well as investigations to obtain information relevant to alleged use.

2. Sampling and transportation, which involves procedures to send materials from the location area to a receiving area, which can be on the site itself or a chemical analysis laboratory elsewhere.

The OPCW, which was established to achieve the object and purpose of the CWC, conducts verification activities and as a result numerous inspections take place. Detection plays a major role during many of the possible inspection scenarios and is a most important component of the health and safety policy of the Organization. This article deals with detection equipment for vapors, liquids, contaminated solids and industrial chemicals as well as explosive or flammable vapor mixtures or lack of oxygen.

1 INTRODUCTION

The Organization for the Prohibition of Chemical Weapons (OPCW), which was established to achieve the object and purpose of the Chemical Weapons Convention (CWC), conducts verification activities and as a result numerous inspections take place. The Organization for the Prohibition of Chemical Weapons (OPCW), which was established to achieve the object and purpose of the Chemical Weapons Convention (CWC), conducts verification activities and as a result numerous inspections take place. Detection plays a major role during many of the possible inspection scenarios and
the right countermeasures, such as wearing protective clothing and a gas mask.

The chemicals of interest to the OPCW are listed in three so-called schedule lists, which are laid down in the Annex on Chemicals of the CWC. These lists not only include CWAs but also many CWA-related compounds.

Within the framework of verification procedures, detection is somewhat similar to detection in the framework of chemical defense, i.e. the detection of CWAs. Many examples exist nowadays of commercially available military equipment that is capable of performing different detection tasks. The various types of equipment include manually operated so-called wet-chemical detection kits, as well as advanced automatic equipment for the detection of certain CWAs. Military detection equipment is usually and increasingly designed to be quick and easy to operate, of limited size and weight as well as robust.

At this point, the use of military detection equipment for OPCW purposes should be considered. Taking into account the scheduled chemicals of the CWC as well as specific requirements for verification purposes as laid down in OPCW’s list of equipment the following conclusions can be drawn:

- Military detection equipment can be used to fulfill a number of required tasks especially in the case of production, storage and destruction of CWAs, during inspections for alleged use as well as at old and abandoned chemical weapon sites.
- Military detection equipment is only suited for the detection of a limited list of CWAs and certainly not all chemicals of interest to the CWC, such as CWA precursors or during industrial inspections.
- Military detection equipment is designed to operate against accepted war-time risks. During peace-time operations, such as during OPCW inspections, the acceptance of casualties resulting from those operations will be much lower. As a result, protection from the use of detectors should be much better than in the case of military use and therefore basic requirements such as response time and sensitivity are more stringent.
- A new generation of detection equipment should be developed in order to detect all CWAs listed in the Schedule 1 list of the CWC.

During OPCW’s preparative period many discussions took place with respect to the choice of the inspection equipment including all kinds of detectors. Eventually, a list of inspection equipment was approved containing operational requirements (general and specific), common evaluation criteria and technical specifications. These equipment items were purchased and are applied during inspections.

In this article, the detection equipment as agreed by the OPCW includes: detectors for CWAs themselves in the form of vapors (section 3), both based on wet-chemical detection principles or physical-electronic techniques; in the form of liquids (section 4), both free-standing liquids as well as liquids present in closed vessels; or in the form of contaminated solids (section 5). According to the OPCW list of equipment for detectors for industrial chemicals (section 6) only detection tubes will be discussed, because the CWC limits industrial chemical detectors to equipment that does not collect samples, i.e. throw-away devices. Section 6 will include detectors for explosive or flammable vapor mixtures or lack of oxygen.

### 2 ROLES FOR DETECTION AND CONCOMITANT REQUIREMENTS

#### 2.1 Roles for Detection

The first and most important role for detection refers to safety. In many cases an inspector’s sensing organs will not be able or sensitive enough to tell him when to take protective countermeasures. This is clearly expressed in Table 1, which lists so-called maximum allowable concentrations (MACs) for short-term exposure of CWAs. The data were derived from the occupational health literature for this type of agent or approximately from the toxic properties of the agents involved. Furthermore Table 1 lists the LS of the agents which have become known from either systematic studies or accidents which have taken place in the past. As can be seen in Table 1 in most cases the LS is higher than the MAC.

LS, limit of smell; L, lewisite-1; HD, sulfur mustard gas; GA, tabun; GB, sarin.
Because an inspector cannot smell the danger he would have to wear protective gear all the time, which is a physical burden and is of course not an option. The only solution is to obtain proper information about the hazardous status of the environment by employing technical means other than using his own nose. This is called detection.

Detection may play an additional role: it relates not only to safety, but also to the location of the area or the object that is most interesting from an inspector’s point of view, in the event that sampling and analysis have to take place during an inspection. Indiscriminate sampling for the different inspection scenarios obviously leads to an excess of samples. Large numbers of samples take a considerable amount of time to analyze, slowing down the inspection process considerably, which conflicts with the, often limited, duration of the inspection. The inspection team must await the results of the analyses before it can act on its findings or discard part of the samples. Therefore the use of detection equipment during an inspection may accelerate the process by acting as a pre-selector to find “hot spots”. The number of samples will be limited or the quality of the samples may increase.

An additional role of detection refers to the screening of samples. One can imagine that during an inspection not all samples are taken as a result of a previous detection, because (rarely) the detector may not be present or the detector may not be easily operable near the sampling site (e.g. because of the location) or when samples are taken in a random way (e.g. when the amount of time is limited). In that case the samples, when collected at a central place on the inspection site, may be screened by using detection equipment in order to be classified in accordance with the detection result. This may be important if a selection of samples has to be made or if priorities have to be applied.

2.2 Specific and General Requirements

In view of the extreme toxicity of the CWAs, it should be obvious that the sensitivity of detectors as well as their response rates should be concomitantly high. This holds especially for detectors that detect CWAs in open contact with the environment. In fact, a dose-related short response time is an important requirement: the detector is allowed to respond a little bit slower at low concentration, because the dose an inspector may obtain in the period during which he is unprotected (response time of the detector plus time needed for putting on protective gear) may be acceptably low. For example, for vapors of nerve and blister agents in air the lower detection limits (DLs) are in the range 5–20 µg m⁻³ and 200 µg m⁻³, respectively, with concomitant response times of less than 2 min and a clear-down time, which is the time needed for the signal to arrive at its original value, of less than 10 min, preferably less than 2 min.

Assuming a detector is sensitive enough and the response is fast, it should also be very selective. On the one hand, when detectors are used for verification purposes, they should be able to detect broad categories of chemicals relevant to the purpose of the inspection. On the other hand they are supposed to show a minimum of false indications. False indications can mean two things. One is called a false positive signal: a signal occurs when there should not be one. This will cause a lot of irrelevant protective measures to be taken. Although this actually leads to some kind of over-protection, in the long run the results may still be dangerous. Through some kind of psychological mechanism people tend to ignore signals when the false signal rate is too high and as a result no protective measures may be taken when a real alarm occurs. The second false indication is called a false negative signal: no signal appears when there should be one. This may be caused by the presence of one or more other chemicals in combination with CWAs or other compounds to be detected. It is quite obvious that the false negative alarm is even more dangerous than the false positive alarm.

On top of the requirements for sensitivity, speed of response and selectivity, there are many general requirements for transportable devices to be employed in the field in toxic environments. These are all listed in the OPCW’s list of equipment³ and include issues such as set-up time, portability, operability by personnel in full protective gear, power supply (preferably battery operable), reliability, low pressure (transport by aircraft), temperature (−25°C to 45°C) and humidity (up to 95% relative humidity (RH)). Chemical hardening, including the possibility for proper decontamination is also important in this respect. Furthermore, data storage by this type of equipment is not allowed, nor may it collect samples in any way nor bring the sampled material outside the inspected area.

3 DETECTION OF CHEMICAL WARFARE AGENT VAPORS

Before World War II the presence of vapors of CWAs or other toxic chemicals was detected with biological indicators such as man’s own nose or the use of small animals (e.g. birds were taken to the battle-field). The days have passed that these methods can be employed to prevent the users from getting hurt.

With respect to detection in the vapor phase, two approaches have been identified. One approach is called the chemical approach, i.e. the application of detection kits. The other, more modern, approach employs physical-electronic devices. Detection kits differ from the physical-electronic devices in their operation: the former are
usually rather laborious to operate. Furthermore, in the case of detection kits, the extensive use of (bio)chemicals may cause problems from the point of view of logistics as well as shelf-life. On the other hand, detection kits are often more selective, although considerable progress is being made with the various physical-electronic systems in that respect. The latter systems are usually faster and more flexible as they may easily be adapted to detect other compounds or classes of compounds.

3.1 Wet-chemical Detection Systems for Chemical Warfare Agent Vapors

According to the OPCW, detection kits employing wet-chemical detection schemes must be able to detect blister agents, nerve agents and so-called blood agents (agents causing blocking of the hemoglobin in the blood) as a minimum. The sensitivity, expressed as a lower DL, should be 0.01 mg m$^{-3}$ for mustard gases, 0.7 mg m$^{-3}$ for nerve agents, 0.07 mg m$^{-3}$ for hydrogen cyanide with a response time of 5–15 min per class of agent.

When using a wet-chemical vapor detection kit, a rather complicated process yields a positive or negative detection result. First of all, a sample should be taken. Air is drawn through an adsorbing material using a manual pump. The adsorbing material may be present in a tube of which both ends need to be broken prior to use or on a little pad, both of which can be placed in front of the pump. Afterwards, one or more reagents are added to the sample according to a fixed procedure. In the case of detection tubes one or more of the chemicals are also present in the tube contained in small ampoules which can be broken successively after sampling has taken place. After some time, a color develops which tells the operator whether the detection result is positive or negative.

Below, in order to illustrate some of the chemistry involved, a number of detection schemes are treated in more detail. Two reaction schemes are shown dealing with the detection of organophosphorus compounds (nerve agents) including the Schoenemann reaction and the enzymatic detection principle. A third detection scheme deals with the detection of alkylating compounds such as mustard gases.

3.1.1 The Schoenemann Reaction

The Schoenemann reaction, originating from 1944, is based on the fact that peroxophosphonates oxidize amines much easier than other peroxy ions, Scheme 1. First, the organophosphorus compound reacts with hydrogen peroxide or sodium perborate in an alkaline solution (pH 9–10). Then the resulting peroxophosphonate reacts with a leuco-dye such as benzidine or $\alpha$-dianisidine to form an orange-brown colored reaction product. In certain modified reactions the amine is replaced by a precursor of a chemiluminescent compound (e.g. luminol) or a fluorescent compound (e.g. indole). The colorimetric variant of the Schoenemann reaction has been applied to many kits using detection tubes or detection pads.

![Scheme 1](image)

The use of enzymes in the diagnosis of diseases is an important benefit from biochemical research and clinical analysis since the 1940s. The real impact of enzymes in chemical analysis was not felt until the early 1960s. In that period the use of enzymes for the detection of all kinds of compounds including so-called anticholinesterases was initiated. During the impact of nerve agents on the human body the active center of the enzyme acetylcholinesterase is phosphorylated. Once the enzyme is deactivated it can no longer fulfill its function of hydrolyzing acetylcholine, which plays an important role in the transfer of nerve stimuli. Consequently, the acetylcholine concentration is increased and the specific symptoms of poisoning appear. The enzymatic detection method employs the enzyme-inhibiting properties of certain organophosphorus compounds. This kind of detection method can be regarded as a first example of a biosensor. In this detection method the naturally involved acetylcholine is replaced by a chromogenic substrate, for example 2,6-dichloroindophenyl acetate (Scheme 2), for that purpose. Normally, the enzyme will catalyze the hydrolysis of the ester group of the substrate, which causes a distinct color change from orange red to blue. As soon as the enzyme is inhibited this hydrolysis reaction will not proceed and the color will remain red. This difference in color between the active and inhibited state of the enzyme can be observed visually but also spectrophotometrically. The latter technique made automated detection of nerve agents possible.
3.1.3 Detection of Alkylating Compounds

Many CWAs other than organophosphorus compounds have in common their strongly alkylating properties, i.e. a good so-called leaving group such as the chlorine atoms of mustard gas, cyanogen chloride, phosgene and L. A detection method employing these alkylating properties especially for the detection of mustard gas was postulated in the 1950s although the related chemistry had been known in the 1920s. As an example the reaction of HD with (4-nitrobenzyl)-pyridine, often called DB3, is shown in Scheme 3. Upon reaction with mustard gas a change from colorless to blue is observed after treatment with caustic soda, whereas reaction with cyanogen chloride yields a yellow-orange color.

\end{align*}
\]

Scheme 3 The reaction of HD with (4-nitrobenzyl)-pyridine.

3.1.4 Detection Kits

The detection reactions described above are being applied nowadays in military detection kits. Within the military context, the content of a specific detection kit is strongly dependent on the operational use that is foreseen as well as correlation with the results of other detection techniques, varying from individual devices to automated detectors, reconnaissance vehicles, remote sensing devices and even field laboratories. As a result the kits differ from each other with respect to the kind of CWA they are designed for, the kind of detection chemistry that is performed, the operating procedures, the sensitivities, the number of detections available per CWA and the lay-out of the kit as well as size, weight, shelf-life and price.

In the introduction it has already been stated that in the context of the OPCW, military detection kits are not always suitable, especially because their DLs are directly related to acceptable risks. Some military detection kits, however, already almost match the sensitivity requirement. In Table 2 the DLs of the current vapor reconnaissance kit in use by the Netherlands Armed Forces are listed as an example. In addition, the table lists the MAC already listed in Table 1 indicating that as a result of compromises related to the military use, the DLs are not always sufficient from a nonmilitary point of view. In order to lower the DLs of this type of wet-chemistry based detection kits one solution is simply to increase the sampling time. As a result more air is blown over the sampling pad or through the tube and more air contaminants are allowed to adsorb. The disadvantage is the increased amount of time needed for sampling as well as the increased number of false positives.

Apart from the rather complicated detection kits, individual hand-held detectors have also been developed, employing the same kind of chemistry. In the military context these are mostly used as end-of-alarm indicators. As an example of an individual nerve-agent detector, the so-called “button” detector was developed by the TNO Prins Maurits Laboratory and has been in use by the Netherlands Armed Forces since the mid 1980s. This cone-shaped detector consists of a plastic holder containing two separated air-permeable reagent papers. One paper (the enzyme paper) is impregnated with the enzyme butyryl cholinesterase, which acts in a similar way to the enzyme acetyl cholinesterase, and silica. The other paper (the substrate paper) contains the enzyme substrate 2,6-dichloroindophenyl acetate (see section 3.1.2). Also, the detector contains a reservoir that releases the reagent solution when punctured. When air is drawn through the enzyme paper, the organophosphorus compounds are adsorbed onto the silica. After some time the “button” is pressed. The reagent solution is released, the reagent papers are wetted and at the same time pressed together initiating the enzymatic detection reaction. After two minutes the blue color of the decomposed substrate

can be clearly observed, or not in the case of a positive detection result. Figure 1 shows the very simple manual device of the Netherlands individual nerve-agent detector. Currently the DL for this device is in the range 0.005–0.020 mg m$^{-3}$ depending upon the kind of nerve gas.

### 3.2 Automated Chemical or Physical-electronic Detection of Chemical Warfare Agent Vapors

Since 1980, several automated chemical or physical-electronic chemical vapor detectors have been developed for military,$^{2}$ industrial or environmental use. Although the systems are usually rather complicated inside, they are easy to handle. The systems have been designed as chemical vapor warning devices in order to tell persons when to take protective measures. These systems usually operate in an automated, continuous, stand-alone way. Other types of equipment often apply the same detection technologies in another way, i.e. as chemical vapor monitors, which are usually hand-held devices. From the point of view of the various CWC verification scenarios, monitors are much more relevant than warning devices. Military warning devices are meant to be operational for a relatively long period of time in a stand-alone mode in order to protect the troops against an attack with CWAs. Military monitoring equipment is used in close vicinity to the user and handled by the user. From the point of view of OPCW’s inspection scenarios this way of using detectors shows more resemblance to warning equipment than the detection devices.

The most important vapor detection techniques currently available for the detection of CWA are based on electrochemical detection, flame photometry and ion mobility spectrometry (IMS) and examples of these techniques are actually used by the OPCW. These techniques are treated in more detail in the section below.

According to the OPCW$^{3}$ the dose-related detection requirements for hand-held vapor detectors are 5 mg s m$^{-3}$ for nerve agents and 10 mg s m$^{-3}$ for blister agents in less than 5 s and 0.5–2.4 mg s m$^{-3}$ for nerve agents and 24 mg s m$^{-3}$ for blister agents in less than 120 s.

#### 3.2.1 Electrochemical Detection

An electrochemical method of detection is based on the fact that some organophosphorus compounds react with certain oximes such as isonitrosobenzoyl acetone (IBA) to liberate cyanide ions under the influence of a hydroxide ion and a good leaving group. In the case of V-type nerve agents a reactive leaving group is introduced upon reaction with a silver fluoride conversion filter prior to the reaction with IBA. The reaction intermediates initially yield one cyanide ion per molecule of CWA. Subsequently, a cyanide ion also reacts with IBA under the influence of hydroxide ions to yield two cyanide ions in return. Thus the initial level of cyanide ions is doubled which can be seen as chemical amplification. The cyanide can then be detected via a colorimetric reaction with p-nitrobenzaldehyde or can be determined electrochemically.

On the basis of this electrochemical method of detection a miniature CWA detector called Individual Chemical Agent Detector (ICAD) has been developed in the USA.$^{2}$ The detector consists of a reusable electronic module (processor, audible alarm and warning light), and a disposable sensor module containing the battery power source and the sensor cells.

Another approach to electrochemical detection is the use of ion-selective electrodes (ISEs). In the case of GB and soman, hydrolysis of the nerve agents yields a fluoride ion that can be detected with a fluoride-selective electrode whereas GA yields a cyanide ion that can be detected with a cyanide-selective electrode.

The enzyme inhibition approach can also be combined with electrochemical detection. When using acetyl or butyryl thiococholine as the substrate, a potentiometric detector can detect the activity of the enzyme. The concentration of converted substrate is a measure of the presence of the enzyme inhibitor.

#### 3.2.2 Flame Photometry

The application of flame photometric detection (FPD) was first reported in 1966 as a selective gas-chromatographic detector.$^{9}$ Normally the concentration of organophosphorus compounds other than CWAs in the atmosphere will be very low. Therefore a more or less
selective method could be developed based on the mere detection of the phosphorus atom using flame emission. When phosphorus-containing compounds are burnt in a hydrogen-rich flame, excited HPO species are formed, whereas sulfur-containing compounds form excited S_2 species. When these species fall back to their ground state light is emitted in the range of 400–550 nm. In particular, the intensive flame emission near 526 nm is attributable to the HPO species and therefore characteristic for phosphorus, whereas flame emission from the S_2 molecule can be measured at 394 nm. Flame photometric devices only detect compounds containing phosphorus and/or sulfur and therefore do not cover the whole range of CWAs and related compounds. In the case of the nerve agent O-ethyl S-2-diisopropylaminoethylmethylphosphonothiolate (VX), which contains both the element phosphorus and the element sulfur, a response is shown in both the “P-channel” and the “S-channel”.

In Figure 2 the basic scheme of an FPD device is shown. Air is drawn into the detection chamber using an air pump. The air contaminants are burnt in a hydrogen-rich flame. In the chamber a photometric cell in combination with optical filters is looking at the light emission phenomena at the relevant wavelengths.

Since the 1970s CWA detectors for military purposes were developed employing this method in a number of countries. The most advanced system nowadays is a hand-held system developed in France, called AP2C, which can be used in a pleasant ergonomic way. The main problem, however, for this type of detection devices is the hydrogen supply, which requires an extra logistic pathway in addition to electrical power, which is used by any kind of physical-electronic system.

DLs for military flame photometry-based detectors are approximately 0.01 mg m\(^{-3}\) for nerve agents and approximately 0.1 mg m\(^{-3}\) for HD with almost real-time responses.

### 3.2.3 Ion Mobility Spectrometry

IMS refers to the principles, practice and instrumentation for characterizing chemical substances through the measurement of gas-phase ion mobilities. Although mobility measurements of gas-phase ions have been studied by physicists since the beginning of the twentieth century, no attempt was made to employ these phenomena for chemical detection purposes. In the 1960s numerous devices employing relatively simple ion separations (i.e. without the use of high vacuum and magnetic fields as in mass spectrometry) were described, mostly in a military context, until in 1970 the development of IMS began. In modern analytical IMS methods, ion mobilities are determined from ion velocities measured in a drift tube with supporting electronics. All processes occur commonly at ambient pressure in air or in nitrogen. Ion mobilities are characteristic of substances and provide a means for detecting and more or less identifying vapors.

In this paragraph a general description of IMS is given. In Figure 3 a schematic layout of an IMS device is shown indicating the reaction region and the drift region. This IMS device is the Chemical Agent Monitor (CAM) used by many armed forces in the world, at our own TNO Prins Maurits Laboratory as well as by the OPCW.

Outside ambient air is drawn into the inlet of the detector by a pump. This air with its possible contaminants first passes through a dust filter and, subsequently, comes into contact with a silicone membrane. The membrane allows some of the target material to permeate whilst excluding (to a higher degree) a number of other contaminants.
found in air such as water vapor molecules. Subsequently, ions are generated by subjecting the permeated air to a $^{63}$Ni radioactive source emitting $\beta$-radiation. The $\beta$-particles ionize the air molecules to form a population of highly mobile positive and negative air ions, the so-called reactant ions, among which are $[(N_2)_x \cdot H(H_2O)_n]^+$ and $[(N_2)_x \cdot (H_2O)_n \cdot O_2]^- (x = 1–3; n = 1–3)$. Charge transfers may happen by multiple collisions of these reactant ions with molecules of contaminants if present in the air. These complicated reactions result in the formation of relatively stable ionic clusters. These so-called product ions are usually relatively large compared to the (air) reactant ions. The ions are swept through the reaction region by an electric field.

Figure 4 represents the formation of a positively charged ion cluster in air containing water (Equation a), and the formation of negatively charged ion clusters in air containing water as a result of ion transfer (Equation b), charge transfer (Equation c) or dissociative charge transfer (Equation d).

Entrance of the formed cluster ions into the IMS drift tube is restricted by a metal grid which acts as a shutter. The shutter grid opens periodically (typically for 0.3 ms in every 30 ms) allowing the ionic clusters to enter the drift region. The shutter grid provides control over the length of the period and the interval between them. An electric field (commonly 200 V cm$^{-1}$) imparts a constant force to the ion clusters leading to separation in accordance with their respective mobilities (commonly 1–2 cm$^2$ V$^{-1}$ s$^{-1}$). Ion velocity is inversely dependent upon the effective collisional cross-section of an ion. This makes IMS an ion-size analyzer. Ions with the highest mobility travel faster and advance in front of those with lower mobilities. At the end of the drift tube the ions collide with a collector giving rise to current pulses. Plotting this current, which is a measure of the intensity of the ions, versus the drift time results in an ion mobility “spectrum”, in the past called a “plasma chromatogram”. Although the latter term better represents the separation of the cluster ions, the technique is nevertheless called spectrometry, which may be confusing from a physical point of view.

The IMS plot will not always show one single peak. First of all, not all reactant ions are converted into clusters and, therefore, a residual reactant ion peak (RIP) is present, which can be used for internal reference purposes. Secondly, one single compound may generate a number of equally stable clusters with different mobilities as a result of their composition, i.e. so-called monomer clusters containing one analyte molecule and some reactant species as well as larger dimer clusters resulting from the interaction between the monomer cluster and one more analyte molecule resulting in a lower mobility (larger drift time). The relative peak height of the various peaks is usually concentration dependent, whereas peak shapes are affected by the complexity of the cluster mixture as well as by the kinetics of the reactions between the clusters as compared to the IMS timescale.

Two IMS modes may be employed: a positive mode detecting positively charged clusters originating from compounds with a high proton affinity such as organophosphorus compounds or a negative mode detecting negatively charged clusters originating from compounds with a high electron affinity such as organochlorine compounds (mustard gases, L).

Figure 5 shows a number of IMS plots recorded by the TNO Prins Maurits Laboratory with a CAM. The IMS plots could be revealed by using dedicated data-acquisition software. Normally, only qualitative and semi-quantitative information (bar level) is provided on a liquid crystal display screen. In Figure 5(a), a positive mode IMS plot of the nerve gas GB (0.2 mg m$^{-3}$ at 45% RH and 22°C) is depicted showing both the monomer and the dimer peak along with the RIP. In Figure 5(b), the negative mode IMS plot of the blister agent HD is depicted (0.6 mg m$^{-3}$ at 45% RH and 21°C). In this plot also a cluster is shown with a mobility larger than RIP. This is the result of HD breaking apart into smaller ions such as Cl$^-$. Figure 5(c) shows the IMS plot of the blister agent L (0.3 mg m$^{-3}$ at 60% RH and 21°C) indicating both a monomer and a dimer cluster as well as a cluster related to the decomposition product.

Owing to the short opening time of the shutter grid, only about 1% of the total ion current is collected. This affects the DL, a disadvantage which is claimed to be more than compensated for by the high selectivity of this IMS technology. This allows the manufacturer to set the alarm levels relatively low, bringing the DL to the required level. The disadvantage of setting the DL low is that in general more interferences may occur. Therefore, a major disadvantage of IMS-based detectors is the poor selectivity. In practice both false positives (signal without analyte present) and false negatives (no signal when analyte is present) tend to occur, especially when the

\[ M + [(N_2)_x \cdot H(H_2O)_n]^+ \rightarrow [(N_2)_x \cdot MH]^+ + n \text{H}_2\text{O} \]

\[ M + [(N_2)_x \cdot (H_2O)_n \cdot O_2]^- \rightarrow [(N_2)_x \cdot M \cdot O_2]^+ + n \text{H}_2\text{O} \]

\[ M + [(N_2)_x \cdot (H_2O)_n \cdot O_2]^- \rightarrow [(N_2)_x \cdot M]^- + O_2 + n \text{H}_2\text{O} \]

\[ XY + [(N_2)_x \cdot (H_2O)_n \cdot O_2]^- \rightarrow [(N_2)_x \cdot X]^+ + Y + O_2 + n \text{H}_2\text{O} \]

**Figure 4** Reaction equation for the formation of positively charged (a) and negatively charged (b, c and d) ion clusters in air with water (M = analyte molecule, X and Y = analyte molecule fragments; $x = 1–3; n = 1–3$).
DETECTION AND SCREENING OF CHEMICALS RELATED TO THE CHEMICAL WEAPONS CONVENTION

Figure 5 IMS spectra of (a) GB (positive mode; 0.2 mg m⁻³), (b) HD (negative mode; 0.6 mg m⁻³) and (c) L (negative mode; 0.3 mg m⁻³). (Data recorded at the TNO Prins Maurits Laboratory.)

Figure 5 IMS spectra of (a) GB (positive mode; 0.2 mg m⁻³), (b) HD (negative mode; 0.6 mg m⁻³) and (c) L (negative mode; 0.3 mg m⁻³). (Data recorded at the TNO Prins Maurits Laboratory.)

sensitivity is set relatively high. Training of operators may be very helpful in dealing with these phenomena. In addition the use of different physical-electronic techniques together with IMS may yield a large synergetic effect in the area of false signal rejection. During many

UNSCOM missions in Iraq, for example, CAM and the flame photometric detector AP2C, operated “hand in hand” in a very satisfactory way. The DLs for military IMS-based detectors are 0.01–0.04 mg m⁻³ for nerve agents and 0.2 mg m⁻³ for HD with response time in the order of 1 min.

With respect to IMS it should be mentioned that all over the world developments are under way aiming at improved IMS, exploring nonradioactive ion sources, improved data-handling systems and miniaturization as well as coupling of IMS to gas-separation techniques such as gas chromatography. In particular, the search for nonradioactive ion sources is important from the point of view of the OPCW because the presence of such a source could potentially cause transport problems on international deployment. Furthermore, dedicated IMS systems for other compounds than CWA are already available, whereas flexibility is increased by using writable memories by which one can easily change from one target analyte to the other.

4 DETECTION OF CHEMICAL WARFARE AGENT LIQUIDS

This paragraph deals with the detection of neat CWA liquids (detection of CWAs dissolved in water is not considered here) including the detection of free-standing CWA liquids as well as so-called nondestructive evaluation (NDE) techniques for the detection of CWA liquids contained in various kinds of vessels. NDE is a screening technique which aims at obtaining more information (including some information about the chemical nature) about the liquid inside the vessel in order to determine if it contains a CWA or not. Depending on the kind of scenario this information is relevant in many ways. For instance the information may contribute to the decision whether sampling, i.e. opening of the vessel and taking a sample, is needed.

4.1 Detection of Free-standing Chemical Warfare Agent Liquids

According to the OPCW, neat liquids of G-type nerve agents, V-type nerve agents and mustard gas should be determined quickly and separately. To detect neat liquids, several types of liquid detection paper, as well as powders or chalks employing colorimetric reactions have been developed for military use. The reactions should not be compared with the relatively complicated reaction schemes in the case of wet-chemical detection of vapors (see section 3.1). In general, the matrix material (paper, chalk, powder) is impregnated with one or more
reactive dyes which develop a color change upon reaction with a CWA. These methods may be especially useful within the context of the verification of alleged use and during inspections of military production, chemical weapon stockpiles or CWA destruction facilities. Liquid detection paper is easily used as an initial screening method for droplets or larger amounts of liquid that are suspected to consist of CWAs. Nerve agents and blister agents are detected quickly in a more-or-less selective way. Some liquid-detection methods are able to detect the three different categories of CWA as mentioned in the requirements of the OPCW with one and the same device, because of the presence of three different dyes impregnated in the matrix.

In contrast to the advanced vapor-detection equipment which exists at the moment there is a lack of direct physical-electronic equipment for the detection of free-standing CWA liquids, especially when small amounts of liquids are lying on the ground or on material or even absorbed in the pores, cracks and crevices of material. Some systems have been proposed to fill this gap, most of them employing active laser-based detection methods, sometimes even preceded by chemical treatment of the surface to generate chemiluminescent compounds as in the case of the Schoenemann reaction mentioned in section 3.1.

It should be clear that from an operational point of view the simple methods for the detection of free-standing liquids or contaminated surfaces do not always suffice. In order to overcome this problem an indirect approach is often used. Assuming any liquid is accompanied by a certain amount of vapor, one could try to reveal the presence of a liquid by tracking down the vapor all the way to the source. This approach only works if the vapors are not evenly distributed in the atmosphere. Only in the case of vapor concentration gradients (plumes) may one track the vapor in the direction of higher concentrations ending up at the source.

At this point it should be stressed firmly that this indirect approach is limited in the case of CWAs dissolved in liquids because the vapor pressure will be much lower in that case allowing only a very small amount of agent vapor to be released into the atmosphere. Also at low temperatures and with agents which possess a low volatility (e.g. the nerve agent VX) or with CWAs that are very strongly adsorbed to the surface, the release of vapor into the atmosphere may be very limited whereas the so-called contact hazard may still be significant. CWAs will still be transferred from the liquid or the contaminated surface through the skin of a relatively warm bare hand.

The OPCW requirements for vapor detectors being able to detect chemicals in a liquid form are 0.01 mg cm$^{-2}$ for nerve agents and 0.08 mg cm$^{-2}$ for mustard gas. Military vapor-detection equipment can be used for this indirect approach. After the proper amount of training, which is even more important in this case than in the case of vapor detection as such, one can use a flame photometric device or an IMS-based device to screen surfaces in a very controlled way in order to follow concentration gradients and hit the liquid spots or the leaking tanks or ammunition.

One can also try to transfer the liquid to the detector by picking it up with an absorbing material and releasing the vapor by heating the material in front of the inlet of a vapor-detection device. Although the number of manipulations is increased and special tools are needed, the chances of locating the liquid or contaminated surfaces in a sensitive and selective way are raised significantly. One of the commercially available FPD devices, the previously mentioned AP2C employs a small battery-powered accessory to absorb liquids and subsequently release them into the inlet of the vapor detector.

4.2 Nondestructive Evaluation of Chemical Warfare Agent Liquids

As stated in the previous paragraph there are several ways to monitor the environment for the presence of CWA liquids. In certain types of inspections, for example at declared or suspected chemical weapons stockpiles, in the case of unexploded munitions or at destruction facilities, an inspection team may be faced with the issue of verifying the contents of a piece of munition, a reactor, a tubing system or a container. Especially in the case of chemical munitions, these scenarios are difficult to deal with. The objects are both chemically and explosively hazardous and therefore safety concerns are very important. Some of the problems an inspector is confronted with are: many chemical munitions appear identical to conventional weapons; agent containers or storage tanks are not unique; munitions can be multi-packed and containerized. Nevertheless, the verification of the contents both qualitatively and quantitatively forms a major task for an inspector. One could try to open the object by drilling or punching a hole to create access to the liquid or facilitate the release of vapor but one can imagine that this may be impossible, very dangerous, at least very time-consuming and require special skilled people (explosive ordnance personnel). Therefore, several techniques have been developed to obtain information about the content of an object without opening or damaging the object. A convenient suite of NDE equipment is available for the characterization of munition fills. Acoustic, X-ray and radiometric techniques will be treated in more detail.

Decisions about inspection alternatives are in general complex because of the numbers and types of objects, storage configurations, inspection objectives and the

level of confidence required. Table 3 summarizes the relationship between information that may be derived, the method employed and the applicable CWA items for the method.

4.2.1 Acoustic and Ultrasonic Detection Methods

As a minimum the human ear can act as an NDE device to determine whether free-standing liquid is present or only solid materials. When tapped with a metal object such items will give a bell-like sound if they are empty or liquid filled. It should be noted that the human ear approach may be somewhat difficult when wearing protective clothing including a gas-mask. Acoustic and ultrasonic systems with their enhanced analysis ability over the human ear, can detect liquid-filled items, determine the fill levels and obtain signatures that can lead to distinguishing the CWA fill type. When other than free-standing munitions are present and when a more direct indication of the fill type is desired, the neutron interrogation systems can be applied.

The major limitation of the acoustic and ultrasonic techniques is that access to the primary wall of the container is required. Shipping containers and packaging effectively preclude the use of acoustic probing techniques.

In the case of acoustic resonance spectroscopy (ARS) objects respond with resonant sound when mechanically excited. Two piezoelectric transducers are used: a transmitter and a receiver. By employing the piezoelectric effect, which is a long-known phenomenon, electrical energy is converted into mechanical energy in the form of acoustical waves by the transmitter. The properties such as frequency (in the 1–30 kHz range) and amplitude of a sweep of acoustic waves with different wavelengths are modulated by the physical properties and geometry of the object the waves meet on their way to the receiver, where the mechanical energy is converted back to electrical energy employing the same piezoelectric effect. In the output spectrum thus obtained signals only become distinguishable (up to two orders of magnitude above the noise level) when a resonance condition is reached, which is determined by the fill and the fill level. As a result the resonance spectrum provides a unique signature for objects and their contents. Because the acoustic signature is based on whole-body vibrations of the object, the exact placement of the transducers on the object is not very critical.

According to the OPCW, ARS must, apart from general requirements, be able to discriminate between solid and liquid-filled munitions with an acceptable degree of confidence and be able to determine the fill level of a container.

Figure 6 shows the response of the nerve agents GB and VX in the same type of projectiles. It should be stressed that this does not mean that some degree of absolute identification can be performed with this kind of equipment. Since the total system is responding, the orientation of the item is not critical and even stand-off excitation is possible. ARS can be best used to measure the degree of similarity between two or more filled items. Thus, if the resonance spectrum of a certain type of shell filled with, for instance, HD is known, the spectra of other shells of the same type with an unknown fill can be compared with it. Furthermore, this method can be employed to determine the thickness of the walls of a container. Especially, in the case of relatively old munitions or storage tanks this will be a very useful approach.

![Figure 6](image-url)
Ultrasonic pulse echo (UPE) interrogation\(^{15}\) of physical structures is a very mature technology. The basic principle of this technique is similar to that of sonar. A high-voltage transducer, coupled to the object to be investigated, provides a square-wave pulse of ultrasonic energy that travels through the wall and into the contents. A search unit made from a piezoelectric material is used to convert the reflected sound waves back into electrical signals. Pulse reflections and times of echo returns are a function of the physical properties of the object. The frequencies used are in the megahertz range. Key characteristics are that pulses are reflected from any material boundary, echoes are returned sooner in the case of solids, and powder fills damp out multiple echoes. All interactions provide indications of the nature of the fill. The simple presence or absence of an echo is a clear indication of whether a fill is a liquid or a solid. The times of the echo returns can indicate structural or fill variations. The level can be determined by sweeping the device alongside the object.

According to the OPCW,\(^3\) UPE equipment must, apart from general requirements, be able to sort like items by comparison of sound propagation time with an acceptable degree of confidence and be able to determine the liquid fill level of a container.

In Table 4 the differences in speed of sound, expressed as their transit times, of the nerve agents GB and VX as well as a surrogate munition (ethylene glycol and water) in 155 mm shells are clearly indicated.\(^{15}\)

### 4.2.2 X-ray Photography

Another way of performing NDE is the use of low-power portable X-ray analysis. Commercial X-ray equipment is available for this purpose. The density of the material which an X-ray, emitted from a source, meets on its way from the source to a detector, determines the amount of radiation that actually hits the detector. This affects the degree of whitening of a photosensitive material. In fact this technique operates in the same way as X-ray photography for medical purposes.

One can employ both X-ray photography or X-ray video. X-ray photography is cheaper and yields better resolution, whereas X-ray videos are more expensive but the operation is real-time and the resolution is adequate.

X-ray photography is routinely used to locate items in overpack containers in order to visualize the presence of steel or at least high-density objects in containers or boxes of plastic or wood. Furthermore, X-ray photography can be used to image the internal structure of munitions (X-rays of 150–300 kV can penetrate steel casings up to 1.5 cm thick) and to assess the presence or absence of buster charges.

X-ray interrogation can also be used to discriminate between solid and liquid contents by looking at the solid–gas or solid–liquid interface. By moving an object such as a shell with respect to the earth’s gravitational field one can easily distinguish a solid from a liquid because the solid–gas interface will hardly move whereas the liquid–gas interface will move as a result of gravitation. This effect is schematically visualized in Figure 7. The information obtained i.e. whether the shell contains a solid or a liquid is an important part of the tiered inspection process as shown in Table 3.

### 4.2.3 Radiometric Detection Methods

Neutron activation analysis (NAA)\(^{16–18}\) is a more powerful NDE technique than acoustic spectroscopy and X-ray interrogation although more time-consuming, costly and subjected to safety regulations. Instrumentation, including portable systems such as portable isotropic neutron spectrometry (PINS), is available for identifying the presence of individual elements indicative of CWAs inside thick-walled steel vessels such as artillery shells and even through secondary containers. Both CWAs and high explosives are rich in the elements carbon, hydrogen and oxygen, but CWAs also contain rather unique combinations of the elements arsenic, chlorine, phosphorus and sulfur. By determining the atomic ratios...
present, phosphorus smoke munition and high explosives can easily and automatically be distinguished from G-type or V-type nerve agent munitions. The detector operates in a near real-time fashion and can be readily operated.

The object to be investigated is irradiated typically with low-energy neutrons (binding energies inside the nucleus are 7–10 MeV, except for hydrogen where it is 2.2 MeV) produced by an isotopic neutron source such as $^{252}$Cf. The source is placed near the munition being surveyed. Each second, approximately one million neutrons are emitted by the source, some of which penetrate the casing and interact with the contents: nuclei are excited and decay promptly (in less than a picosecond) to the ground state with the emission of characteristic $\gamma$-rays. With a high-purity germanium $\gamma$-ray detector, requiring constant low temperature (77 K), the energies and intensities of $\gamma$-rays released by neutron interactions are measured. The energy of the $\gamma$-radiation is characteristic of elements present in the object. In Table 5 a number of characteristic energies are shown as well as the relative elemental composition in a number of CWAs. These energies have been measured and cataloged since the mid 1950s.(19)

Figure 8 illustrates the difference between the $\gamma$-ray spectrum of mustard gas in a ton container and that of a high explosive in a 155 mm shell. Some difficulty in easy access to randomly chosen items, such as shells at the back of a bunker or in the middle of a stack can be envisaged. Furthermore, the presence of a radioactive source could potentially cause transport problems on international deployment. According to the OPCW(3)

</table>
For fast and large-scale screening of objects an important NAA method is based on hydrogen concentration measurement (HCM). In this method fast neutrons are emitted from a neutron source ($^{252}$Cf). Upon collision with protons, the neutrons slow down into so-called thermal neutrons which are in thermal equilibrium with the environment. The neutrons can leave the object and be measured by a detector, usually consisting of a scintillator converting neutron energy into light and a photomultiplier tube for amplification of the light emission. Under controlled circumstances the number of neutrons detected per unit of time relates to the number of hydrogen atoms per unit of volume. Therefore, calibration for each type of object and fill is required.

Without HCM the ratio of elements such as the P/S ratio cannot be accurately determined with a single measurement, for hydrogen significantly diminishes the flow of fast neutrons. A typical measuring time is less than one minute compared to the 30-min measuring time of other NAA methods. With HCM even discrimination between, for instance, different nerve agents or high explosives can take place provided the contents are relatively pure. On top of that, because HCM is so fast, the fill level may also be measured in this way, especially when UPE fails in the case of double-walled containers where the required contact between the object under investigation and the transducer is not possible.

One major drawback of the HCM technique is the fact that L can not be detected very well because of its very low hydrogen content.

According to the OPCW, the HCM must be capable of determining hydrogen concentration within the fill of munition items or other containers at an accuracy of better than 10%. Furthermore, it must be capable of allowing discrimination between explosives and CWAs such as nerve gases or mustard as well as discriminating between representatives of the latter class of agents.

5 DETECTION OF SOLIDS CONTAMINATED WITH CHEMICAL WARFARE AGENTS

At present, there are hardly any direct detection methods to determine whether solid materials are contaminated. Relatively large amounts of suspect liquids can at least be observed visually, but a hazard resulting from contaminated solid materials cannot always be observed in the same way because the CWA may be absorbed or adsorbed, whereas the contact hazard is still considerably high. Therefore, for solid materials, the level of protection should be raised and gloves must be used at all times.

An indirect approach is the monitoring of the surrounding air with a vapor-detection system. However, this presents the same limitations as mentioned in section 4.1 for the indirect detection of liquid CWAs. The reader is referred to section 4.1 for further information about the use of vapor detectors for the detection of contaminated solids or for the checking of decontaminated solids.

6 DETECTION OF INDUSTRIAL GASES OR VAPORS

In the previous paragraphs the emphasis was put on the detection of CWAs. However a number of inspection scenarios are not CWA related, but they may also take place in a toxic environment generating safety problems. Although in general toxicity may not be as high as in the case of CWAs, the scope of chemical hazards which may be encountered by an inspector will be very wide. In the chemical industry safety of personnel is a very important issue. Within the field of occupational safety and health many toxic chemicals or classes of chemicals have been identified and a lot of toxicological information has been generated in order to set exposure limits for people working in environments containing those chemicals. As in the case of protection against CWA one has to detect a hazard in order to protect oneself against it. Therefore detection equipment for many different chemical hazards has been developed and is being sold commercially and used on a large scale. The same general problems apply, such as selectivity, sensitivity, false-alarm rates, stand-alone compared with manually operated equipment, that were discussed for CWA vapor detection and equipment.

A basic subdivision of the field is made into direct-reading colorimetric indicators and direct-reading instruments. From the point of view of the OPCW currently two classes of equipment are very important: direct-reading colorimeters, especially glass detection tubes, and equipment for the detection of flammability and of explosive vapor mixtures or lack of oxygen as well.

6.1 Glass Detection Tubes

According to the OPCW, glass detection tubes are to be used to test the environment for the presence of toxic gases or vapors. The detection should be indicated by the length or shade of color change of the detector tube after sampling and shown some kind of concentration indication in ppm, mg m$^{-3}$ or % volume. After being used the tubes are thrown away.

Glass detection tubes containing solid and/or liquid chemicals are convenient and compact detectors. During the past decades there has been a great expansion in the development and use of these tubes. Several companies are employing a number of basic reaction schemes for
DETECTION AND SCREENING OF CHEMICALS RELATED TO THE CHEMICAL WEAPONS CONVENTION

the detection of many organic and inorganic compounds. Some reactions are amongst others:

- reduction of chromate or dichromate to chromous ions for the detection of alcohols, aldehydes, ketones, esters, hydrocarbons or sulfur dioxide;
- reduction of iodine pentoxide with fuming sulfuric acid to iodine for the detection of aromatic hydrocarbons, acetylene, carbon monoxide or vinyl chloride;
- reduction of ammonium molybdate with palladium sulfate to molybdenum blue for the detection of ethylene, butadiene, hydrogen sulfide and sulfur dioxide;
- reaction with potassium palladysulfite for the detection of carbon monoxide or hydrogen cyanide;
- color change of pH indicators for the detection of acidic and alkaline compounds;
- reaction with o-toluidine for the detection of chlorine or chlorinated organic compounds, bromine or nitrogen dioxide;
- reaction with tetrphenylbenzidine for the detection of halogens, halogenated organic compounds, nitric oxide, or acetonitrile.

The use of these detection tubes is extremely simple. Before use, both ends are broken and the glass tube is placed in a dedicated holder which is fitted with a squeeze bulb or piston pump. Subsequently, the recommended air volume is drawn through the tube by the operator, closely following the manufacturer’s instructions. After this the operator reads the concentration in air by examining the exposed tube. The length of the colored stain is a semi-quantitative measure of the concentration.

In some cases direct sampling may be a problem. Then the tube may be placed near the sampling point and the pump is operated at some distance. A rubber tube extension with the same inside diameter as the sampling tube may be inserted between the detector tube and the pump. When hot air samples need to be taken, cooling may be essential. In that case a special probe of glass or metal may be attached to the inlet of the tube. When employing special accessories it is very important that the air components are not being adsorbed on the materials used. Therefore the previously mentioned rubber extension is placed between the tube and the pump and not in front of the tube.

The selectivity of the tubes is a major consideration with respect to the applicability and the interpretation. In some cases the lack of selectivity permits detection of a class of chemical compounds rather than a single compound.

Although detection tubes are usually advertised as being capable of use by unskilled people and the operating procedures are indeed very simple, many limitations and potential errors are inherent in this method. The results may be dangerously misleading and sometimes need to be supervised by a well-trained person.

Figure 9 shows an example of the lay-out of a detection tube for hydrogen cyanide, a toxic industrial chemical also placed on the CWC schedule list. The detection range is 5–50 ppm for two pump strokes and 2–12 ppm for 10 pump strokes. The analyte is reacting with mercury chloride to yield hydrogen chloride which causes a pH-sensitive dye to change from blue to yellow. The type of reaction employed is not sensitive for hydrogen, hydrocarbons and carbon monoxide up to 50 vol.%, carbon dioxide up to 15 vol.%, halogenated hydrocarbons, nitriles, carbon disulfide and acetic acid up to 1 vol.%, ammonia and sulfur dioxide up to 1000 ppm and hydrogen sulfide and hydrogen chloride up to 300 ppm.

6.2 Detection of Explosive Vapor Mixtures, Flammability or Lack of Oxygen

According to the OPCW, the purpose of a flammability/explosive/air-quality monitor is to allow safe entry into and stay in confined spaces with potentially flammable/explosive atmospheres or insufficient air quality.

A general chemical hazard which does not relate to a specific chemical compound is the presence of combustible gases, i.e. the hazard that a mixture of oxygen and one or more chemical compounds (hydrogen or volatile hydrocarbons) might explode upon some kind of ignition mechanism. Explosive mixtures sometimes behave very subtly with respect to ignition. A very simple human action taking place inside or near the gas mixture such as a scratch or a spark resulting from static electricity may cause the mixture to explode.

A somewhat related issue is the lack of oxygen. As a result of a combination of the lack of fresh air flowing through a building or a similar construction and the release of gases or vapors driving out the oxygen or smoldering fires or biological activities consuming the oxygen, the amount of oxygen may no longer be sufficient.
for inspectors to operate normally, causing an important safety and health risk.

Within the framework of a number of CWC-related inspection scenarios it is possible for an inspector to be confronted with explosive mixtures or oxygen deficiency. Inside closed or more-or-less closed buildings or bunkers, near storage sites, abandoned sites or chemical plants, all of which may be partly damaged, the hazards described may be present. Again, as in the cases described in the previous sections, one should be capable of protecting oneself by way of, amongst others, leaving the site, flushing the atmosphere with fresh air or consuming pressurized air. Specific detection equipment is to be used to tell the operator if and when the hazard exists.

Many companies sell different explosive-vapor monitors, but they employ more-or-less the same operating principle. Most combustible- or explosive-gas detectors are based on the principle that gases will react with oxygen in the presence of a heated catalyst mounted on a pellistor. Oxidation of a gas further raises the temperature of the pellistor causing, in turn, an increase in the resistance, which is detected by a Wheatstone bridge and indicated on the display as a gas concentration. This detection principle has some limitations as some specific gas mixtures may poison the catalyst. Lead gasoline and certain compounds containing silicone are suspect in this respect. For this reason and because of the fact that the lower explosion limit (LEL) may differ from one gas to another, explosive-gas detectors have to be calibrated frequently and tuned in on the LEL of the worst case to be expected. New developments in the field of catalysis have improved the catalysts with respect to the risks of being poisoned. In the commercial literature the following vapors which can be detected employing this technique, are mentioned: aldehydes, alcohols, esters, saturated and unsaturated hydrocarbons, ketones.

Oxygen in the air is usually detected by the electrochemical operating principle in the 0–25% oxygen range. A number of instruments combine explosive-vapor detection and oxygen detection in a general-purpose detector.

Fourier Transform Infrared in On-site and Off-site Analysis of Chemicals Related to the Chemical Weapons Convention

Martin T. Söderström
Finnish Institute for Verification of the Chemical Weapons Convention, University of Helsinki, Finland

1 INTRODUCTION

Infrared (IR) spectroscopy is one of the oldest instrumental analytical techniques but its value in structural analysis has decreased somewhat with the rise of NMR spectroscopy and MS. Compared to the traditional dispersive IR techniques, FTIR offers more sampling techniques.

In the analysis of environmental samples, all kinds of chromatographic techniques are necessary because the sample matrices can be very complicated. So far, the best commercially available IR technique for environmental analysis is gas chromatography/Fourier transform infrared spectroscopy (GC/FTIR). The association of GC/FTIR with different gas chromatography/mass spectrometry (GC/MS) methods is a valuable tool in analysis of environmental samples. The power of FTIR is that it gives very characteristic spectra, which can be used almost like fingerprints.

The Chemical Weapons Convention (CWC), which came into force in April 1997, contains provisions for chemical analysis of samples in both on-site and off-site laboratories. On-site laboratories will be manned by the inspectors of the Organization for the Prohibition of the Chemical Weapons (OPCW) and equipped with the analytical equipment approved by the states that are party to the OPCW. Off-site laboratories will analyze ambiguous samples which on-site analysis cannot resolve. These research laboratories are equipped with sensitive instruments and are designated by the OPCW on the basis of performance in proficiency tests.

Chemical warfare agents (CWA) are classified into several categories, e.g. nerve agents and vesicants. Tear gases are forbidden as a method of warfare but are allowed for riot control purposes. The CWC lists chemicals in three Schedules, which have been constructed on the basis of the toxicity of the chemicals, their industrial use and historical usage as warfare agents. Schedule 1 consists of families of toxic chemicals, which have been developed, produced, stockpiled or used as chemical weapons, e.g. sarin and mustard gas. These chemicals have very little industrial use. Schedule 3, on the other hand, consists of 17 single chemicals with very large industrial use, e.g. phosgene and triethanolamine.

There are challenges in the CWC-related analysis. Even though the Schedules restrict the number of possible target chemicals, the number of chemicals is still more...
than 10,000. The properties of the chemicals vary from solids to gases and from volatile to nonvolatile chemicals. In IR the absorptivities vary considerably.

One challenge in the analysis of the CWA is the analysis of precursors and degradation products, which are often nonvolatile. The CWA degrade, e.g. hydrolyze or oxidize, quite easily. Traditional IR sampling techniques, like KBr pellets and liquid cells, are well suited to analysis of neat or quite concentrated nonvolatile chemicals. Environmental samples containing these kinds of chemical, however, normally require derivatization before GC/FTIR analysis.

In the field of CWC-related analysis, chemicals can be identified by comparing their spectra with spectra in spectral libraries or with spectra measured from authentic chemicals. Spectral interpretation is not enough for unambiguous identification but it is an important tool in structural elucidation of unknown chemicals.

As usual in analytical chemistry, a combination of the results of several different analytical techniques gives the most reliable results. In a well-equipped off-site laboratory, results from FTIR, MS and NMR, together with other analytical data, can be combined to produce reliable, unambiguous analytical proof to support chemical disarmament.

Good books are available on some of the subjects discussed in the article, for example, on the following subjects: chromatography FTIR,41 FTIR spectroscopy in general42,3 and IR spectra of phosphorus-containing chemicals.44

2 SAMPLE PREPARATION

Many of the chemicals related to the CWC are very toxic, and therefore care must be taken while handling samples that may contain these chemicals.

Different sample preparation or introduction methods in IR can be divided into two categories: methods where no sample separation takes place and methods where the sample undergoes separation prior to FTIR measurement. The former class (e.g. KBr pellets), liquid or gas cells, and attenuated total reflectance (ATR), can be used only for relatively pure and concentrated samples, e.g. bulk materials. The latter class (e.g. GC) is required when analyzing environmental samples or mixtures where the target chemical is not concentrated. The American Society of Testing and Materials (ASTM) has published a standard practice describing different general IR spectroscopy techniques.45

There are restrictions in the selection of the sample preparation or introduction method when the laboratory is taken on-site. Methods requiring supplies difficult to provide in field conditions, typically liquid nitrogen, cannot be applied on-site. Thus, GC-based and ATR methods are not normally applicable on-site. A suggestion for a basic on-site sample preparation kit is shown in Table 1.

The physical state of the chemical to be analyzed determines which sample preparation method is selected. The majority of the chemicals listed in the Schedules of the CWC are liquids in room temperature. There are also chemicals which are gases or solids, in each schedule. Some chemicals are borderline cases, which may be solids at room temperature but melt in the IR beam or may be liquids that are too volatile in the IR beam. Table 2 summarizes some typical chemicals of each type in the Schedules.

Sample introduction using GC solves many problems related to the analysis of chemicals related to the CWC. The amount of chemical needed is quite low, which almost removes the danger of handling these chemicals. A drawback in the GC is that it can only be used to analyze volatile chemicals. Volatile derivatives can be made from most of the nonvolatile Schedules chemicals.

2.1 KBr Pellets and Liquid Cells

Most solid or liquid chemicals related to the CWC can be analyzed using KBr pellets or liquid cells.

The preparation of KBr pellets is a standard procedure in laboratory conditions since the hydraulic press used for pressing is standard equipment. In an on-site laboratory, the press is not a very practical tool because it weighs about 50 kg. If a press is a necessity on-site, the possibility of using a hand-held KBr press should be considered.

2.1.1 Solid Samples

There are several techniques for preparing solid samples for IR analysis: solid KBr pellets, melts, solutions and mulls. While analyzing chemicals related to the CWC, introduction of additional absorbance bands in the spectra should be avoided. Therefore, the last two methods should not be used if other methods are available, since they always have peaks present due to solvent or oil.

If no equipment for preparing the KBr disks is available on-site, other methods that do not use solid KBr disks must be chosen. Solid chemicals form a minority in CWC-related chemicals. These chemicals could be prepared on-site, e.g. by dissolving them first in a suitable solvent, depositing a couple of droplets on a KBr disk, and then evaporating the solvent off. The spectra obtained in this way are not of the best quality and it is not normally a recommended procedure under laboratory conditions, but is often sufficient for identification as shown in Figure 1(c).

Thorough instructions for preparing solid KBr samples are presented by Dent. The article also includes trouble shooting for the preparation of KBr disks.

When measuring spectra of very hard crystals, sometimes, distorted bands, almost like those found in derivative spectra, can be seen with solid KBr or a mulling technique. This is caused by the Christiansen effect which appears if crystals that are too large are left in the sample after grinding. The IR beam is reflected from the crystals, and as the refractive index changes over an IR band the peak shape is distorted. If the crystals are ground more so that the particle size becomes smaller than the wavelength of the IR radiation (2.5–25 µm in the mid-IR region), no distortion appears. Figure 1 shows the Christiansen effect in the spectrum of tear gas CR (CAS 257-07-8). First (Figure 1a) the sample grinding was deficient and the Christiansen effect was clearly visible. After this, the sample was extensively reground, resulting in a nondistorted spectrum (Figure 1b). Atmospheric water had been introduced to the sample during the regrinding. For comparison, spectra obtained by a dissolution–deposition–evaporation method (Figure 1c) and by GC/FTIR (Figure 1d) are shown.

2.1.2 Liquid Samples

Generally, the analysis of pure liquid chemicals is very straightforward. Liquid chemicals with a boiling point below 100 °C should generally be analyzed in a sealed cell (preferable for CWC-related analysis) or in solution. Other chemicals (bp >100 °C) can be easily analyzed between KBr pellets. CWC-related chemicals should be considered very toxic, by default, and therefore extra care should be taken in their analysis, to avoid the vapor hazard.
Measuring the IR spectra of liquid chemicals is relatively simple, if commercial KBr windows for liquid cells are available. These windows can be reused if cleaned and decontaminated effectively. Decontamination solution containing potassium hydroxide and ethanol works effectively, but it also corrodes the windows extensively. The decontaminated windows often need polishing to make them fully transparent and smooth again.

In the case where the windows must be guaranteed to be clean, new windows should be used each time. However, this can become quite expensive if a large number of samples is to be analyzed. In such a case, the use of a press for preparing KBr pellets should be considered.

2.1.3 Safety

Always when handling CWC-related chemicals, safety must come first. Sample preparation must always be carried out in a fume cupboard. Protective gloves should always be used and a respirator should be kept available for emergencies. Work on live agents should not be performed alone; there should always be somebody who oversees the person handling the toxic chemicals.

An airtight sampler holder or at least an outer container for the sample should be used when possible. The spectrometer can be placed in a fume cupboard to avoid vapor hazard, but good ventilation of the sample compartment can be enough. It should be remembered that sample preparation should not be carried out in the same fume cupboard, to avoid contamination of the instrument. Decontamination of a FTIR spectrometer is very difficult, if not impossible.

The work area should be kept as tidy as possible to enable safe sample preparation. It is a good idea to use trays in the fume cupboard. These are easy to clean and decontaminate and also they contain any spillage of chemicals.

A good practice is to monitor the workspace inside the fume cupboard with a continuous hand-held or table-top chemical agent detector, if such a device is available. There are several models commercially available, based on ion mobility, flame photometric, enzymatic or photoacoustic detection.\(^9\)
2.2 Attenuated Total Reflectance

ATR is a technique based on total internal reflections at the crystal surface. In a way, the IR spectrum is measured from a very thin film surrounding the IR transparent ATR crystal. This technique is one of the best IR sampling techniques suitable for analyses of chemicals in water. The detection limit is less than 1 mg mL$^{-1}$ for nerve agents.$^{(10)}$

The sampling cell with the crystal can be also a flow through cell, which makes the sample handling easier.

The use of an ATR accessory normally requires a mercury-cadmium-telluride (MCT) detector to achieve enough sensitivity. The detector requires liquid nitrogen cooling, which limits the on-site usage of this method.

2.3 Gas Cell

Gas cells can be used for gaseous and volatile liquid samples. The use of the gas cell is simple, but care should be taken in emptying the cell, since the sample may be very toxic. A gas sample can be sucked into an evacuated cell from the atmosphere or from a container containing gas, if a suitable connection is available. Volatile liquid samples can be placed as droplets into the cell, which is closed, and the chemical can be allowed to vaporize. The gas phase spectrum can then be measured. The droplets can be also placed in a separate bottle for vaporization, and the vapor can then be transferred into the evacuated gas cell.

The difficulty in gas sampling is that the spectra differ from condensed phase spectra. Therefore, reference spectra of gas phase spectra are required for accurate identification.

In principle, the cell should not need cleaning, other than emptying it, after the analysis, since only the gaseous phase is measured. However, one should be certain that all possible volatilizable chemicals are removed from the surfaces before the next measurement. The KBr windows of a gas cell may require polishing after use, especially when used in humid conditions.

2.4 Gas Chromatography

In general, GC is very well suited to analysis of very toxic volatile chemicals since the analyzed quantities can be very low. Normal injection volumes with capillary columns are 1–2 µL. Most of the CWA are volatile, and their nonvolatile degradation products can be made volatile through derivatization (e.g. methylation or silylation).

There are three different types of GC/FTIR interface: light-pipe, matrix isolation (MI), and cryodeposition (also direct-deposition, cryotrapping). All three have been used for the analysis of CWC-related chemicals. The light-pipe interface has been the most popular, and it is available from several manufacturers. At present, there are no GC/MI/FTIR (gas chromatography/matrix isolation/Fourier transform infrared spectroscopy) instruments available commercially but there used to be the Cryolect® system from Mattson. The usage of cryodeposition in this type of analysis has been increasing over the years, even though it is available from only one manufacturer (Bio-Rad Tracer®).

ASTM has published a standard practice for GC/FTIR analysis, covering basic features of each type of interface.$^{(11)}$

2.4.1 Light-pipe

The light-pipe interface is the easiest method of connecting a GC and an FTIR spectrometer. The light-pipe is a long flow cell with reflective inner coating and IR transparent windows at both ends of the cell. It is very easy to operate and to maintain. The problem with the light-pipe interface is that it is not very sensitive compared to a normal benchtop mass spectrometer, and this makes the analysis of same samples difficult. The IR spectra of the chemicals are measured in the vapor phase, as the GC effluent is hot. One of the problems associated with the spectrum measurement in the gas phase is that a gas phase spectrum of a chemical differs considerably from those measured in other phases. See section 3.3 for further discussion of this subject.

2.4.2 Cryodeposition

Cryodeposition is the newest interface type for a GC/FTIR instrument. In this system, the eluents in the GC effluent are frozen on an IR transparent slide which is cooled using liquid nitrogen. The carrier gas evaporates in the process so that the chemicals are directly deposited on to the slide surface. Transmission spectra are then measured through the slide. These spectra are like normal condensed phase spectra, with rare exceptions. The sensitivity is five times better than in a light-pipe and the same or even slightly better than in GC/MI/FTIR.

Since the principle of the cryodeposition instrument is based on depositing the eluting compounds in very small spots (ca. 100 × 100 µm) on the depositing surface, all large amounts deposited on the surfaces will interfere with the operation of the system by spreading too widely on the surface. For this reason, the eluent exiting the deposition tip must be directed to a solvent sink (i.e. away from the slide) until the solvent has eluted. The wait time for solvent is controlled by a parameter, the “solvent delay”. This necessary delay in starting the data collection means that all the chemicals eluting before the solvent or any other large peak has eluted are missed.
2.4.3 Comparison of Interfaces

Using either GC/MI/FTIR or cryodeposition, GC/FTIR spectra can normally be obtained from the same environmental samples (concentration, e.g. 1–10 ppm) as in GC/MS. The chromatograms produced by GC/FTIR instruments differ somewhat from those in GC/MS because in IR the absorbance varies greatly depending on the chemicals. However, the same chromatographic peaks can be located in the different chromatograms.

GC resolution degrades slightly in all of the available GC/FTIR interfaces. In the light-pipe type interface some broadening of the chromatographic peaks occurs because the diameter of the light-pipe (often 1 mm) is larger that of a capillary column (0.25–0.5 mm). Thus the GC resolution degrades by an average factor of 1.2. In the MI and cryodeposition interfaces there is spreading of the chromatographic peaks owing to the deposition of the sample on a surface causing the GC resolution to decrease by an average factor of 1.8.

It is also possible to combine GC/MS and GC/FTIR instruments so that two analysis results can be obtained with one injection. This type of system is cost effective, but from the analytical point of view not always recommended. Neither of the instruments can be used fully. If the GC/FTIR interface is of the light-pipe type, the concentration requirements are not met with most of the chemicals. In some instruments, the GC effluent is split 1 to 10 between MS and FTIR. The result can be that the sensitivity of the MS is lowered, but still FTIR is not sensitive enough.

The speed and sensitivity of the measurement needs a MCT detector to be used in a GC/FTIR instrument. Additionally, MI and cryodeposition techniques use at least liquid nitrogen to enable the trapping of the eluents. The need for cold liquids renders the GC/FTIR methods logistically difficult.

2.4.4 Derivatization

The most common derivatization methods in the analysis of chemicals related to the CWC are methylation with diazomethane (CAS 334-88-3) and silylation with either N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA; CAS 25561-30-2) or N-methyl-N-(tert-butyldimethylsilyl)trifluoroacetamide (MTBSTFA; CAS 77377-52-7). The former method changes hydroxyls of acid groups to methoxy groups and the latter method changes hydrogens of hydroxyls to trimethylsilyl (TMS) or tert-butyldimethylsilyl (TBDMS) groups. Figure 2 demonstrates the effect of the two derivatization methods on methylphosphonic acid (CAS 993-13-5).

The advantages of methylation are that the sizes of the derivatized chemicals do not increase very much and the dissolved derivatization reagent does not change the chromatogram very much. One of the disadvantages is that this method does not derivatize alcohols, which sometimes are difficult to analyze with nonpolar columns like SE-54 (5%-diphenyl–95%-dimethylsiloxane), which is commonly used in this type of analysis. Additionally, the group added to the molecule, methyl, is a naturally occurring group. It is impossible to know from the methylated sample alone if the chemical in it originally contained the hydroxyl or methoxy version of the...
chemical. For confirmation of this, analysis of the underderivatized sample is also required.

Silylation results in a more complicated sample than methylation, but it also shifts the derivatized chemicals to longer retention times. As the TMS group does not come from natural sources, the original chemical in a sample can be deduced without comparison with an untreated sample. Silylation enhances retention characteristics of chemicals much better than methylation. It also silylates active sites of the column material. However, when starting to analyze silylated samples with a cryodeposition system, the solvent delay time must be increased to avoid deposition of a large amount of early eluting residue of derivatization reagent present in the sample after the reaction. This results in loss of chemicals eluting simultaneously with the reagent.

Before an injection of a derivatized sample, care must be taken to ensure that the injection system is cleaned of derivatizable chemicals from previous injections. These might be derivatized by the derivatization reagent and elute giving false positive results. A good way to check the cleanliness of the system is to inject 1–2 µL of the derivatization reagent solution.

2.5 Other Techniques

There are some liquid chromatography/Fourier transform infrared spectroscopy (LC/FTIR) instruments commercially available, but there are so far no published applications on the analysis of chemicals related to the CWC. The analysis of water-soluble degradation products would be a suitable area for use of this method. It would not be logistically viable to take a LC/FTIR instrument on-site.

IR microscopy, diffuse reflectance infrared Fourier transform spectroscopy (DRIFT) spectroscopy and photoacoustic spectroscopy (PAS) techniques may be suitable for some types of sample but the use of these methods for analyses of CWA has not been reported.

Promising studies have been published on the use of remote detection of CWA, but they are outside the scope of this article.

3 DATA EVALUATION

When IR is used for identification of chemicals from CWC-related samples, it is important to verify or at least compare the results with those from different analytical techniques. Especially, when environmental samples are analyzed using GC/FTIR, results should be compared with results from GC with selective detectors and GC/MS. These techniques are very powerful in chemical identification when used together in a collaborative manner. This requires the use of similar GC conditions and columns. It has been a standard practice to require consistent results from at least two different analytical methods to confirm unequivocal identification. These methods can include among others GC retention index monitoring, gas chromatography/electron ionization/mass spectrometry (GC/EI/MS), gas chromatography/electron ionization/high-resolution mass spectrometry (GC/EI/HRMS), gas chromatography/chemical ionization/mass spectrometry (GC/CI/MS), gas chromatography/chemical ionization/tandem mass spectrometry (GC/CI/MS/MS), GC/FTIR and NMR (1H (proton), 13C(1H) (proton decoupled carbon-13), 19F, 31P, and 31P(1H) (proton decoupled phosphorus-31)).

One question regarding the data measured during an on-site analysis is the confidentiality of commercial and defense data. It is not in the interests of the chemical industry to allow analytical information on their processes to be made public. Such problems can be resolved by including only spectra relevant to the inspection in the instrument’s database. However, if spectra are measured so that the analyst can see the spectra and print them, there always is a possibility that an experienced analyst can identify the chemical, even if its spectrum is not included in the instrument’s database. A so-called blinded-software is used in the mobile mass spectrometer used by the OPCW to overcome this problem. This software has been developed in the National Institute of Standards and Technology (NIST) in the USA. However, no such software has been developed for FTIR, so far.

After the analysis itself, there are several steps to the final result. In GC/FTIR the peaks of the analytes of interest must be located from the chromatogram. The chemicals must then be identified by comparison with existing data or if this is not possible the spectra should be interpreted so that reference material can be obtained or synthesized.

3.1 Gram–Schmidt Chromatogram

In GC/FTIR, the chromatogram representing the absorbance of each scan set versus retention time is called the Gram–Schmidt chromatogram (GSC). The GSC resembles the total ion chromatogram (TIC) in MS and a flame ionization detection (FID) chromatogram. It is not a simple sum of all absorbances of a spectrum, but calculated using interferograms as vectors. This technique is faster than first performing a Fourier transform and then integrating the spectrum. Normally in GC/FTIR, the interval between consecutive data points has to be about one second to achieve the necessary chromatographic resolution. This one-second left for the calculation of a data point in a chromatogram used to be beyond the capabilities of the computer.
The GSC differs from a TIC in MS or a FID chromatogram. The relative intensities of the chromatographic peaks are sometimes very different in IR, due to differences in absorptivities between chemicals. For example, chemicals containing phosphorus–oxygen bonds have high absorptivities. Additionally, as the chromatographic resolution is lower in GC/FTIR, closely eluting peaks may overlap in IR, but not in MS or GC.

The software of some instruments uses a threshold for storing GC/FTIR data. This means that only data on peaks above a set threshold are stored. This approach is not generally recommended for analyses of environmental samples when the concentration of the target analytes is not known in advance. It is important also to be able to examine the spectra of minor components.

### 3.2 Functional Group Monitoring

A useful practical procedure in GC/FTIR is functional group monitoring. During the data collection or, in some systems, just after it, absorbance of certain selected spectral regions in each spectrum is plotted against the retention time to produce new chromatograms, functional group chromatograms (FGC). This enables the chromatographic peaks of interest to be selected in an easier way than by using the GSC.

Many chemicals related to the CWC contain functional groups which give rise to strong, characteristic absorption bands. These are summarized in Table 3.

#### Table 3 Summary of the most characteristic functional groups of the chemicals related to the CWC. Many of these groups can be used as a basis for FGC. Wavenumber regions are based on data from Söderström(8) and Bellamy(15)

The use of functional group monitoring will make it possible or at least easier to find the target chemicals in the midst of background chemicals. For example, likely background chemicals in samples from a battlefield or industry could be those from gasoline, diesel fuel, rubber and paint or even humic acids. These chemicals can mask the target chemicals by overlapping and make the sample too complex to be able to identify each peak in the chromatogram. Figure 3 shows an example of an extract of a rubber sample containing two mustard agents. In the functional group chromatogram 750–680 cm⁻¹, the peaks of the two agents can be seen clearly.

### 3.3 Reference Spectra and Spectral Libraries

In the FTIR analysis of the chemicals related to the CWC, the spectral libraries are essential. For the purposes of the CWC, there has to be a reference spectrum for identification. If there is no IR reference spectrum available, the identification cannot be accepted unless a reference compound can be synthesized and a reference spectrum measured.

#### 3.3.1 Available Reference Data

There are no commercial libraries available which contain more than some occasional CWC-related chemicals. So far, each laboratory has been forced to create its own IR libraries but, since, 1994 the OPCW has collected...
Figure 3 Chromatograms of an extract of a rubber sample containing two mustard agents (peaks marked with 2 and 3): (a) GSC and (b) functional group chromatogram 750–680 cm⁻¹. (Reproduced by permission of the Finnish Ministry for Foreign Affairs from (1992) Rautio, Figure 16, p. 312.)

Some IR spectra of chemicals related to the CWC can be found in open literature. The largest collection of spectra can be found in two of the so-called Blue Books of the Finnish Institute for Verification of the Chemical Weapons Convention (VERIFIN) published in 1977 and 1982. Blue Books describing the results of international interlaboratory comparison tests also contain some example spectra. Shagidullin et al. have published an IR atlas of organophosphorus chemicals which contains spectra of some relevant chemicals. Several articles contain IR spectra or spectral data for nerve agents and related chemicals and vesicant related chemicals.

3.3.2 Spectral Differences Caused by Sample Introduction

The phases of the chemicals measured in light-pipe and cryodeposition instruments are different: vapor and condensed phase, respectively. The intermolecular interactions are different in the two phases (i.e. missing in the vapor phase) and therefore, for example, all hydrogen bond-related vibrations are missing or different. Also, the vibration bands are narrower in the gas phase. Thus, the spectra cannot be compared with each other. Traditional IR spectra measured using salt pellets or windows also produce condensed phase spectra, which are therefore comparable with cryodeposition spectra (see example in Figure 4). There are other differences caused by factors of more practical nature: lower sensitivity and resolution. Owing to all these differences, two sets of reference spectra have to be measured.

The light-pipe spectra are usually measured at the resolution of 8 cm⁻¹ with 4 co-added scans, whereas the cryodeposition are often rescanned to a resolution of 4 cm⁻¹ with 64 to 512 scans. Figure 5 shows light-pipe reference IR as well as mass and NMR spectra. These spectra are to be made available for states that are party to the Convention, i.e. countries which have ratified the CWC.

Figure 4 Part of cryodeposition (solid line) and liquid phase (dotted line) spectra of O-ethyl S-(2-(dimethylamino)ethyl)methylphosphonate. (Reproduced by permission of American Institute of Physics from M.T. Söderström, ‘Identification of VX-type Nerve Agents Using Cryodeposition GC-FTIR’, in Fourier Transform Spectroscopy, 11th International Conference, ed. J.A. de Haseth, American Institute of Physics, New York, USA, 457–460, 1998.)

Figure 5 Spectra of thiodiglycol. (a) Light-pipe spectrum at 8 cm⁻¹, (b) cryodeposition spectrum at 4 cm⁻¹. (See Söderström.)
and cryodeposition spectra of thiodiglycol. MI spectra differ considerably from both light-pipe and cryodeposition spectra since the molecules are normally isolated molecules in noble gas matrix at very low temperatures. Thus, the spectral peaks are very sharp due to loss of intermolecular interactions and low rotation in the molecules.

More than 90% of the IR spectra collected by the OPCW are in the condensed phase. The largest commercial condensed phase IR library (Sadtler Condensed Phase IR Standards library) has over 75,000 spectra, while the largest vapor phase library (Sadtler Vapor Phase IR Standards library) has less than 10,000 spectra. There are no commercial MI libraries available.

3.3.3 Quality of Reference Spectra

To make the identification of chemicals unambiguous, some kind of criteria for acceptable reference spectra are needed. All reference spectra should be evaluated using acceptance criteria. The OPCW rules require that at least three evaluators agree on the spectrum before it is accepted. The evaluation criteria defined by the OPCW are the following:

- The spectrum must be consistent with molecular structure of the chemical.
- The spectrum must show the absence of extraneous spectral features attributable to impurities or contaminants.
- The sample preparation method for the measurement must be stated.
- The minimum resolution must be 4 cm$^{-1}$ for condensed phase and normal gas phase spectra, and 8 cm$^{-1}$ for GC light-pipe spectra.
- The minimum spectral range must be at least 3700–700 cm$^{-1}$.
- The signal-to-noise ratio must be adequate to detect all relevant peaks.
- The largest absorbing peak must not be saturated.
- The spectra must be adequately compensated for atmospheric carbon dioxide and water.
- The intensity of the bands arising from water contained in the sample should be less than 5% of the highest intensity absorption band of the sample.
- For inclusion in the central OPCW Analytical Database, a spectrum must fulfil at least one of the following criteria:
  
  (a) It is consistent with IR data of the same chemical from another source.
  
  (b) It is supported by accepted NMR or MS spectra obtained from the same sample with consistent results.

For the submitted reference spectra the OPCW requires that the following data is attached to the spectra:

- OPCW code for the spectrum (assigned by the OPCW),
- contributor’s name and address,
- contributor’s signature,
- chemical information,
  - chemical name
  - CAS registry number (if available)
  - chemical structure
  - molecular formula (optional)
- sample information,
  - sample purity (optional)
  - source (optional)
  - sample phase
- instrument information,
  - type (Fourier, grating or prism)
  - manufacturer
  - model
  - data system (optional)
  - Software version (optional)
- experimental information,
  - sampling mode (liquid, solid, solution, gas, light-pipe, cryodeposition, bulk, micro)
  - measurement mode (transmission, absorbance, reflectance)
  - baseline correction (manual, automatic, none)
  - matrix
  - detector (optional)
  - wavenumber range
  - indication of the ordinate scale
  - resolution
  - number of scans (optional)
  - date of experiment (optional).

3.4 Library Search

Searching the spectrum of an unknown chemical against a spectral library is routine method used to identify chemicals. Most of the commercial IR instruments include library search software which has several search algorithms to choose from. The search algorithm can sometimes have a very strong effect on the library search result. This is because of the different ways in which the actual comparison between the spectra is done. Particularly when the library and the unknown spectra have been measured differently (e.g. using solid KBr disk and cryodeposition GC/FTIR), the IR band shapes and positions may vary slightly. In these cases, the choice of proper search algorithm is essential.
Two of these search algorithms are least-squares metric (also called Euclidean) and derivative least-squares metric (also called derivative Euclidean). In both algorithms the unknown and library spectra are normalized before the comparison. In the least-squares metric algorithm, the intensity difference between the corresponding data points in the spectra is raised to the second power. The sum of these differences is the hit quality index (HQI). The derivative least-squares metric algorithm is based on differences in the intensity change between two consecutive data points instead of the intensity of each point. There are many ways to apply the algorithms and to present the HQI, so that it is impossible to give any estimates for a value for a good library match. The derivative least-squares metric algorithm is much more sensitive to changes in band position, which means that it should be used when the phase of the unknown and the library spectra are the same.

Figure 6 demonstrates an IR library search. The unknown chemical was dimethylethylphosphonate (DMEP) measured using cryodeposition GC/FTIR. The library was a cryodeposition spectrum library. If the derivative least-squares metric algorithm (HQI can be 0–999; 999 is perfect match) is used the result is DMEP (HQI = 558), dimethylpropylphosphonate (DMPP) (HQI = 275), dimethylisopropylphosphonate (DMIP) (HQI = 246) and dimethylmethylphosphonate (DMMP) (HQI = 216) as shown in Figure 6. The least-squares metric search gives a slightly different result: DMEP (HQI = 861), DMPP (HQI = 744), DMMP (HQI = 632) and DMIP (HQI = 607). Note that the first case gives a much better indication of the correctness of the search result, by giving a bigger difference between the first and the second hit.

The search result should never be accepted based just on the result listing, but should always be verified visually. It is therefore necessary for the analyst to have at least a basic knowledge of which spectral features to look for. When the analyst is required to differentiate between very closely related chemicals, e.g. nerve agent homologs, more knowledge of the particular chemicals and the origin of the spectral bands is a prerequisite.

Identification in spectra of mixtures is always somewhat difficult. Spectral subtraction can sometimes be used to reduce the complexity of the spectrum by removing the features of the subtracted spectrum. Subtraction seldom gives clean spectra but it can at least help the final identification.

3.5 Interpretation

For the purposes of the CWC, results obtained with two spectrometric techniques are required for identification.

Figure 6 Example of library search. An unknown chemical was searched against a library containing chemicals related to the CWC. The first hit, DMEP, was clearly the best candidate and matches the unknown. The search algorithm was a square derivative and the maximum HQI value is 999. (See Söderström.8) CAS numbers are given in parentheses.
of a compound. Although very useful as such, the interpretation of IR spectra does not identify the chemical but may give tentative structures. Interpretation gives excellent results in some cases, but it should always be remembered that the accuracy of interpretation depends on the type of the chemical and the experience of the scientist. In the case when an unknown compound is encountered, spectral interpretation (MS, IR, and NMR) is required so that the reference chemical can then be synthesized.

In the interpretation of IR spectra of chemicals related to the CWC, it should be remembered that for some chemicals, e.g. nerve agents, a structure could be proposed very easily and accurately. For some other types of chemicals, e.g. mustards and other vesicants, only the chemical class can be proposed. This is because some functional groups do not have good structure-specific group frequencies. Such spectra can only be used as a fingerprint for the chemical.

3.5.1 Phosphorus-containing Chemicals

L.C. Thomas and R.A. Chittenden have carried out a thorough series of studies on the identification of organophosphorus compounds. The group frequency tables in these studies enable interpretation of many of the characteristic features in the spectra of nerve agents and related chemicals. Several structure–spectrum relationships give specific information on the molecule. One very valuable relationship discovered by Thomas is the dependence of the position of the P–O bond stretching vibration (in wavenumbers), \( \nu_{P=O} \), on the substituents on the phosphorus, represented by \( \pi \) constants (Equation 1):

\[
\nu_{P=O} = 930 + 40\sum \pi
\]

The \( \pi \) constants have been determined experimentally from over 900 compounds for a wide variety of substituents (91 substituents). Table 4 summarizes the most important groups that are present in the chemicals relevant to the CWC and their \( \pi \)-values. Most of the calculated values are within \( \pm 12 \text{ cm}^{-1} \) from the experimental values. For example, for sarin the calculated value is \( 1280 \text{ cm}^{-1} \), while the experimental values are \( 1277 \text{ cm}^{-1} \) and \( 1272 \text{ cm}^{-1} \) for liquid and cryodeposition spectra, respectively.

The alkyl groups connected to phosphorus or to oxygen next to phosphorus can be identified in many cases. One of the most characteristic bands is the P–Me deformation near 1300 cm\(^{-1}\). There is also the P–Me rocking band near 900 cm\(^{-1}\). The bands of the other P–alkyl group do not give characteristic bands but can be identified by comparison with spectra of similar chemicals. Bands for P–O–Me (near 1180 cm\(^{-1}\)) and P–O–iPr (three bands, 1100–1200 cm\(^{-1}\)) are characteristic. P–O–alkyl vibrations can also be identified by comparing patterns produced by known groups to those in the unknown spectrum. A summary of some of these P–O–alkyl group patterns is shown in Figure 7.

In phosphonofluoridates, there is always the P–F stretching band. The range given by Thomas for this vibration in sarin analogs is 858–833 cm\(^{-1}\).

Some of the chemicals related to the CWC contain tertiary amine groups. The type of alkyl group (methyl, ethyl, propyl or isopropyl) can be deduced in some cases from the stretching of the C–H next to the nitrogen atom. The value of the asymmetric stretching is lowered due to the interaction with lone pair electrons of the nitrogen atom, so that the bands of this vibration are separated from the normal C–H stretching bands. Figure 8 shows some typical peaks of this kind in the VX-type chemicals.

One very characteristic peak for tabun-related chemicals is the stretching of the C≡N bond. A sharp band due to this vibration can be seen at 2200 ± 2 cm\(^{-1}\). There is always a band in the spectra of tabun homologs, due to the P–N–Me group near 1320 cm\(^{-1}\). This band occurs very close to the P–Me deformation band in, for example, sarin, homologs. In the tabun homologs, however, the peak near 900 cm\(^{-1}\) due to P–Me rocking is missing.

Often, IR spectra can be only partially interpreted. An example of interpretation of the spectrum of sarin is shown in Figure 9. In the interpretation of a spectrum of organophosphorus chemical, it is very important first to deduce the type of chemical. In the spectrum presented, the position of the P=O stretching band (1272 cm\(^{-1}\)) is typical of sarin-type chemicals. A very strong band typical for P–O–C is present at 1020 cm\(^{-1}\). When there is also a peak matching the P–F stretching at 838 cm\(^{-1}\) as well as the P–Me peaks at 1322 cm\(^{-1}\) and 927 cm\(^{-1}\), the chemical seems to be an alkyl methylphosphonofluoridate. As the peak pattern in

Figure 7 A summary of some P–O–alkyl groups. R1 is P–alkyl and R2 is P–O–alkyl). The compared compounds belong to the sarin (1; alkyl alkylyphosphonofluoridates), the tabun (2; dialkylamino alkyl phosphoramidocyanidates) and the dialkyl methylphosphonate (4) families. There are two peaks (1185–1180 cm\(^{-1}\) and 1072–1070 cm\(^{-1}\)) in the tabun family (2) spectra in addition to the C–O peaks. These peaks are due to the C–N bond. The dialkyl methylphosphonate compounds (4) listed here are symmetric (R\(^2\)=R\(^3\)). (Reproduced by permission of Springer-Verlag from M.T. Söderström, R.A. Ketola, *Fresenius’ J. Anal. Chem.*, 350, 162–167 (1994).)
the region 1250–1050 cm\(^{-1}\) matches the P–O-isopropyl patterns shown in Figure 7, it is proposed that the structure is isopropyl methylphosphonofluoridate, i.e. sarin.

In the analysis of chemicals related to the CWC, spectral interpretation is not done with only one type of spectra. Often MS or NMR spectra are used together with IR spectra in the elucidation of the structure of an unknown chemical. There are some examples of this type of elucidation available in the literature.\(^{(4,25,26,44)}\)

One must remember that there are important spectral bands, which do not fit in the narrower detector range (e.g. 4000–700 cm\(^{-1}\)) of a GC/FTIR instrument with a MCT detector. In CWC-related organophosphorus chemicals, e.g. the bands due to P–S–C and P–Cl bonds, are at too low frequencies to be seen in the spectra. The P–S–(C) frequency is 573–520 cm\(^{-1}\) in VX-type chemicals and the general P–Cl frequency is 587–420 cm\(^{-1}\).\(^{(4)}\)

### 3.5.2 Nonphosphorus Chemicals

Nonphosphorus chemicals related to the CWC are more or less difficult to interpret. There are functional groups with characteristic vibrations in many chemicals, but the structure cannot be elucidated fully by interpreting the IR spectra as is the case with e.g. nerve agents. Table 3 contains some of the characteristic vibrations in nonphosphorus chemicals related to the CWC.

A partially interpreted cryodeposition spectrum of 2-(diisopropylamino)ethanol (CAS 96-80-0) is presented in Figure 10. In this case, the full structure cannot be deduced from the spectrum. There are two
bands indicating the presence of C–OH group in the molecule: stretching of C–O bond at 1035 cm\(^{-1}\) and the double peak of the hydrogen-bonded O–H stretching at 3375 and 3230 cm\(^{-1}\). In the tracer spectra, the hydroxyl stretching band seems to appear as two bands in the symmetric dialkylaminoethanols.\(^{8}\) In asymmetric dialkylaminoethanols and in liquid phase spectra (band shown in Figure 10) the vibration appears as one band. The presence of isopropyl can be detected from the presence of two bands at 2875 and 2607 cm\(^{-1}\) and two bands at 1382 and 1361 cm\(^{-1}\). The former peaks are due to the (N–)C–H stretching, as in VX-type chemicals (shown in Figure 8) and the latter peaks to the methyl stretchings in the \(-\text{CH}(\text{CH}_3)_2\) group. The lack of other characteristic bands indicates the presence of a scheduled chemical, 2-(diisopropylamino)ethanol. Further confirmation for this is, however, required.

4 APPLICATIONS

There are relatively few recent articles published on the FTIR analysis of CWC-related chemicals. Most of the research is old or unpublished.

4.1 International Tests

One of the best ways of testing methods and competence in the field of CWC-related analysis have been the international tests organized first by VERIFIN and later by the OPCW. Eleven tests were carried out during 1989–1998,\(^{16,19–22,45–48}\) FTIR has not been used by many laboratories in the tests, as the laboratories with fewer resources have been concentrating on GC/MS analysis, e.g. because of the lack of GC/FTIR instruments. The maximum number of GC/FTIR instruments used in the test was eight out of 26 laboratories. On average, laboratories using cryodeposition GC/FTIR instruments have performed better GC/FTIR analysis. In the beginning, some laboratories used nonhyphenated FTIR instruments but the results were poor when analyzing environmental samples. It should be noted that in the interlaboratory comparison test in 1991,\(^{20}\) FTIR was used successfully without GC separation. The test samples were not environmental but organic solution samples, for which FTIR is very suitable.

International tests have shown that a GC/FTIR instrument is not a necessity for a successful analysis because two other techniques (GC/EI/MS, GC/CI/MS, NMR or even GC retention index monitoring) can be used as the required alternative techniques. The major advantages of GC/FTIR are that it gives information on different characteristics of a chemical than, for example, MS and NMR and it can make the overall spectral elucidation much easier and faster, and the first “guesses” more accurate (see Söderström et al.\(^{25}\) for examples). The latter advantage is emphasized when analyzing phosphorus chemicals.

In international tests false identifications have occurred on the basis of misinterpretation of MS or NMR spectra only, e.g. isopropyl methyl ethylphosphonate (CAS 141968-53-8) has been identified instead of methyl propyl ethylphosphonate (CAS 170082-59-4),\(^{46}\) and methyl propyl ethylphosphonate instead of the methylation product of butylphosphonic acid (i.e. dimethyl butylphosphonate; CAS 24475-23-8).\(^{22}\) These mistakes were due to matching molecular weight, similarity of the spectra and the lack of reference data, and could have been avoided by using additional techniques, such as GC/FTIR.

There are of course limitations to interpretation capability with some chemical types. For example, spectra of mustard-gas-type chemicals cannot be interpreted to produce an unambiguous analysis result. In the first official OPCW proficiency test,\(^{45}\) there was a sample where three mustard-type chemicals (spectra shown in Figure 11) were present: sesquimustard (CAS 3563-36-8), 1,3-bis[(2-chloroethyl)thio]propane (CAS 63905-10-2) and 1,5-bis[(2-chloroethyl)thio]butane (CAS 142868-94-8). In this case, reference spectra existed only for the first two compounds. The identity of the third could not be proven (only inferred) because a reference spectrum was not available. The spectrum and retention time definitely indicated the correct answer but they are not enough for an unambiguous identification.

4.2 Attenuated Total Reflection Applications

Braue and Pannella\(^{10}\) used a flow-through ATR cell for quantitative measurement of tabun, sarin and soman in water. The sample change and measurement could be performed safely, owing to quite dilute samples and airtight fittings. The method they developed has the useful range of 0.5–2.0 mg mL\(^{-1}\). Quantitation is based on P=O stretching near 1240 cm\(^{-1}\).

Parchment et al.\(^{49}\) used a diamond ATR probe to monitor decontamination of mustard gas, sarin, soman and VX. They conclude that because of the relatively low sensitivity of the method, it can only be used for analysis of CWA in realistic concentrations in real time and in situ.

The breakthrough of mustard gas and mustard ether (CAS 63918-89-8) in different types of rubbers\(^{50}\) and polypropylenes\(^{51}\) has been studied using ATR as one of the analysis techniques. One side of the material was exposed to the agents while the unexposed side was against the ATR crystal.

4.3 Gas Chromatography/Fourier Transform Infrared Applications

Both Söderström et al.25 and Creasy et al.26 have applied GC/FTIR along with several other hyphenated chromatographic techniques to analyze chemical weapons-related chemicals in complex matrices. The results from the different techniques have been combined to identify unequivocally the relevant chemicals in low concentrations. In both studies, IR and MS spectra have been used together in spectral interpretation. Weimaster et al.52 studied samples collected in Iraq, using a wide variety of instrumentation, but they could not find any scheduled chemicals.

Danian et al.27 report structural identification of a VX-type chemical using GC/MS, NMR and GC/FTIR. They concluded that the identification of the chemical based only on MS data is very difficult. The use of NMR and FTIR data makes the identification more reliable.

Durst et al.29 performed a microscale synthesis of several sarin analog autosampler vials and analyzed them directly with a gas chromatography/infrared spectroscopy/mass spectrometer (GC/IR/MS) instrument. They presented a couple of light-pipe IR spectra and a table of typical gas phase frequencies for 12 sarin-type chemicals.

Sokolowski and Szymańska30 analyzed tabun, which had been stored at least 20 years, with a GC/IR/MS instrument. The sample was analyzed first in the underivatized form. Then portions of it were methylated or silylated and analyzed. They reported nine light-pipe IR spectra of derivatized degradation products.

Goeringer and Elizy31 used GC/MI/FTIR to analyze alkylphosphonic acids from simulated river water samples. The chemicals were silylated before the analysis.

Smith et al.34 studied three isomers (cis-, trans- and geminal) of lewisite using GC/MS, GC/FTIR and NMR. Söderström et al.43,53 studied interpretation of spectra of some organophosphorus chemicals as well as their IR and retention index searches. Some example spectra, chromatograms and interpretation are given.

5 QUALITY CONTROL

One aspect in the work of the OPCW is the use of designated laboratories where samples collected during an inspection could be sent for analysis. To be able to rely on the results provided by the designated laboratories, their performance must be rigorously tested. This is the purpose of the OPCW proficiency tests. In order to become a designated laboratory the laboratory must have a national accreditation (ISO/IEC Guide 25, EN 45001 or equivalent). If FTIR is to be used in accredited analysis, the laboratory must have written procedures for testing the performance of the instrumentation and for the analysis. The purpose of these tests is to guarantee high quality and reliability of the results.

The procedures can be adapted from standards or from the instrument manufacturer, and they can be defined by the laboratory.

For example, ASTM has described a two-level procedure for testing the performance of an FTIR spectrometer.54 The routine check of instrument performance, the zero-level test, includes the following tasks:

- measurement and comparison of background against a previously measured background,
- measurement of a hundred per cent line (HPL) and
• measurement and comparison of the spectrum of a polystyrene sample against a previously measured spectrum.

The more extensive tests, level-one tests, include six tests which facilitate the diagnostics of the instrument:
• energy spectrum test
• HPL
• stability test
• signal-averaging test
• polystyrene sample test and
• photometric jitter test.

The performance of the GC must be tested regularly, e.g. daily, to ensure that the column retains no previously analyzed chemicals. When samples containing free acids are analyzed, e.g. soil samples containing humic acids, the column should be tested before other types of samples. When the column performance degrades, the column should be changed, or at least part of the column from the beginning should be replaced with a new piece of column. In order to lengthen the life of the columns, especially because of acidic injections, an uncoated inactivated precolumn can be used before the actual analytical column. There is a published Recommended Operating Procedure (ROP) for testing the performance of a GC system in the analysis of chemicals related to the CWC.\(^{12}\)

All the solvents used must be checked before the analysis, and during the analyses relevant solvent blanks must be used to test the cleanliness of the system. When analyzing derivatized samples, it is not enough to use just the solvent; the derivatizing chemicals should also be added to the solvent to ensure that there are no derivatizable chemicals in the system before the actual analysis.

If a blank is supplied for each sample, as often has been the case in international tests so far, they should be analyzed before the samples. It should be remembered that in realistic cases no blank samples are available or that the blank and the sample have totally different backgrounds, e.g. water coming in to a factory (blank) and wastewater (sample with possible chemicals).

There should also be some criteria for the quality of spectra. OPCW has used criteria for the reference spectra (see section 3.3.3). These criteria can also be used for sample spectra where applicable.

6 COMPARISON WITH OTHER ANALYTICAL METHODS

In an analysis of a complicated sample, GC/FTIR alone cannot fulfill the identification criteria, just like any other analytical technique. Results from one technique can be correct but consistent results from other techniques are required for the final proof of the correctness.

Compared with GC/FTIR, GC/EI/MS gives comparable chromatograms, but is generally a more sensitive technique. The structural information provided by GC/FTIR and GC/EI/MS differs, so that they complement each other well. For example, there are cases when EI/MS (electron ionization/mass spectrometry) cannot differentiate between isomers but FTIR can, and cases where FTIR cannot give the exact size of an alkyl group but EI/MS can. These techniques also give overlapping structural information, thus increasing the reliability of the identification. Normally, commercial EI/MS spectral libraries are much cheaper and larger than FTIR spectral libraries. Therefore, it is easier routinely to identify chemicals present in the samples by GC/EI/MS and disregard the uninteresting chemicals after a match has been found from a library.

GC/CI/MS usually gives information on molecular mass. It can also give more information on some substituents if CI/MS/MS (chemical ionization/tandem mass spectrometry) is used. The molecular weight information becomes more important as the size of the molecule increases, since FTIR cannot easily distinguish between the sizes of longer alkyl groups.

Other mass spectral techniques which use liquid chromatography (LC) and capillary electrophoresis (CE) as the sample introduction method make it possible to analyze chemicals which should otherwise be derivatized for GC analysis and also those nonvolatile and nonderivatizable chemicals which cannot be analyzed at all with GC. Many of these chemicals could be analyzed with FTIR without GC separation, but, in the environment, they may be in, e.g. water or soil samples (which possibly have to be extracted with water). Water samples are difficult to analyze with FTIR, since water is quite a poor solvent for FTIR due to very high molar absorptivity.

NMR is one of the most important tools in structural elucidation, but since the technique cannot be hyphenated with GC like MS and FTIR, and its sensitivity is poorer, it cannot always identify chemicals from high background samples. The unchallenged capability of NMR to give information on connectivity and neighboring atoms makes it a very desirable method in the analysis of chemicals related to the CWC. NMR can for instance normally find out the type of the carbon (methyl, ethyl, propyl, or isopropyl) directly connected to phosphorus (\(^{1}H\) and \(^{31}P\) spectra) and the presence of the fluorine–phosphorus link (\(^{1}H,^{19}F,\) and \(^{31}P\) spectra). Different two-dimensional-NMR experiments give additional information on connected atoms.

FTIR is a valuable addition to the instrumentation for a laboratory which is expanding its capabilities beyond just the basic necessities (GC and GC/MS). The effective
and complementary combination of analytical techniques based on different principles, e.g. as in IR, MS, and NMR, gives a solid base for any type of instrumental analysis. It is essential for the analysis related to the CWC that the analysis results are reliable and indisputable.

Various gas chromatographic methods, which are useful for the screening of Chemical Weapons Convention (CWC)-related chemicals, are described in this section. Proper choice of columns, detectors, and injection techniques are discussed, because they are crucial to the optimization of gas chromatography (GC) as a routine tool. Also various identification methods are described. Retention index monitoring (RIM) is described in more detail than other identification methods because it is the most reliable GC technique to be used in the identification using a retention index (RI) library without the need for an authentic chemical.

1 INTRODUCTION

GC is the most widely used single analytical technique for the analysis of volatile organic compounds. The advantages of GC are good resolution, inertness, high sensitivity and possibilities for selective detection. Although the use of GC with conventional GC detectors has decreased due to the decreased prices of benchtop GC/mass spectrometry (MS) instruments, GC together with selective detectors still has an important role in the analysis of chemicals related to the CWC. Most of these chemicals have sufficiently high vapor pressure and thermal stability for GC analysis or they can be easily derivatized to a volatile form using methylation, trimethylsilylation, tert-butylidimethylsilylation or pentafluorobenzylolation. Witkiewicz et al. have published a comprehensive review concerning various chromatographic applications for the analysis of CWC-related chemicals.

GC has been the main separation technique in the international interlaboratory comparison and proficiency tests. All participating laboratories used GC, either to determine the retention behavior of analyzed compounds or as part of the hyphenated techniques. It has been agreed based on these tests that the unambiguous identification of CWC-related chemicals has to be based on at least two different analysis techniques, preferably by two different spectrometric analysis techniques, when available, giving consistent results. The minimum acceptable data are the correct electron impact mass spectrometry (EI/MS) spectrum together with the correct retention data. GC/EI/MS spectra and retention parameters obtained with the same instrument are not regarded as two different techniques.

In verifying the absence or presence of CWC-related chemicals, the analysis of a specified sample includes analyzing samples by different chromatographic and spectrometric techniques. In general, the chromatographic techniques together with conventional detectors are useful for screening and tentative identification and analyses are in most cases rather qualitative than quantitative. GC methods used for screening purposes should be sensitive and selective and should detect as many CWC-related chemicals as possible in one GC analysis. Sensitivity can be obtained by specific detectors and selectivity by including a database in the GC computer containing identification data of relevant chemicals. GC monitoring before gas chromatography/mass spectrometry (GC/MS) identification, especially when done with specific detectors, is important in producing useful information from complex mixtures. When a lot of samples must be analyzed, GC can be used either to pick out the most valuable samples for more thorough analysis or to optimize the concentration of the samples for GC/MS identification.

2 INSTRUMENTATION

2.1 Sample Introduction

Injection techniques play an important role in chromatographic separation. Split, splitless, and on-column
injection methods have been studied\(^1\)\(^5\) in order to optimize peak shapes, detection limits, and detector response reproducibility for CWC-related chemicals. Splitless injection at 250 °C with a splitless time of 45–60 s and using the hot-needle technique with a solvent flush was the most suitable injection method giving satisfactory results even for samples with difficult matrices. However, on-column injection has some advantages over other techniques, especially in the analysis of thermolabile compounds, high boiling compounds or compounds with adsorptive properties. The molecules will enter the column relatively slowly at a temperature that is lower than their boiling points. Detection of VX (CAS 50782-69-9) and its homologues and most of the methylated degradation products of nerve agents give better results by on-column injection: the detection limits for VX were about 50 pg with on-column injection and 2 ng with splitless injection when the same OV-1 column was used.\(^6\) However, for environmental samples such as soil and plant extracts on-column injection may lead to rapid contamination of the analytical column. A changeable precolumn coupled with a press-fit connector can be used to protect the analytical column from contamination. In addition, an autosampler cannot always be used with the on-column technique. The split technique provides good separation efficiency for most volatile compounds such as hydrogen cyanide (CAS 74-90-8), phosgene (CAS 75-44-5), and cyanogen chloride (CAS 506-77-4) when the concentrations of these are high enough. However, discrimination against high boiling components is evident.

The large-volume injection technique together with on-column injection\(^1\)
\(^7\)
\(^8\) and thermal vaporization injection\(^1\)
\(^9\)
\(^10\) has been used to improve the sensitivity of GC analysis. Several hundred microliters of the sample can be injected by this technique. Degenhardt-Langelaan et al.\(^2\)\(^1\) determined selected nerve agents at parts per trillion levels in organic extracts of water samples using large-volume injection. Although this method is very attractive, the optimization of all instrument parameters is quite time-consuming.

Cold trap injection is normally used in the analysis of air samples. During the thermal desorption from Tenax\(^8\) resin\(^2\)\(^3\) the sample chemicals are collected on a cold trap, after which the temperature of the cold trap is quickly raised to about 250–300 °C. The chemicals move as a narrow band to the capillary column for a normal gas chromatographic run without an interfering solvent peak. The usefulness of the thermal desorption method for the analysis of CWC-related chemicals has been tested.\(^2\)\(^3\) The recoveries at low nanogram levels were between 81% and 103% for sarin (CAS 107-44-8), soman (CAS 96-64-0), tabun (CAS 77-81-6) and mustard gas (CAS 505-60-2) when the volume of sampled urban air was between 5 L and 30 L. VX (CAS 50782-69-9) could not be detected due to its high adsorptivity nature. The breakthrough volume of sarin, one of the most volatile nerve agents, was 60 L at the sampling temperature of 23 °C on 100 mg Tenax\(^8\) adsorbent. Tenax\(^8\) tubes loaded with some organophosphates and mustard gas from humidified atmospheres have been stored for up to 2 months without a decrease in recovery.\(^2\)\(^4\) Hancock et al.\(^2\)\(^5\) developed an automated air sampling analysis system for the monitoring of CWC-related chemicals in air. Air samples were collected on minitubes packed with Tenax\(^8\) TA and thermally desorbed into GC without cryofocusing. A RIM method together with thermal desorption has been reported.\(^2\)\(^3\),\(^2\)\(^6\),\(^2\)\(^7\) RIs were determined by loading a Tenax\(^8\) tube with the monitored chemicals and subsequently with a series of index standards.

2.2 Run Conditions

According to the recommended operating procedure for the analysis of CWC-related chemicals by GC\(^2\)\(^2\) when using SE-54 or OV-1701 columns (25 m × 0.32 mm inner diameter (ID), 0.25 µm film thickness) the following conditions are recommended: injector temperature, 250 °C; detector temperature, 280 °C; temperature program, initial temperature 40 °C for 1 min, temperature programming rate 10 °C min\(^-1\) to 280 °C for 10 min. However, the GC conditions depend on the injection techniques used, columns, sample types and the analytical demands: when GC is used for rapid sample screening or when maximum resolution is needed, the GC conditions are different.

2.3 Columns

The most critical parameters of a capillary column are resolution, support inertness, retention reproducibility, thermal stability, and bleed. To provide fast, reliable and accurate analysis, it is important that the stationary phase. ID of column, film thickness and length of column be chosen with a view to the particular application. CWC-related chemicals differ greatly from each other in their chemical and physical properties and thus the selection of the stationary phase is always a compromise between resolution and analysis time. The most suitable stationary phases for the separation of chemicals related to the CWC are listed in Table 1, along with their structures, and polarities.\(^2\)\(^2\)

The nonpolar phases tend to have better characteristics in terms of resistance to oxygen, higher efficiencies, and greater maximum temperatures. Laboratories should have in their use at least two columns of different polarity. The SE-54 phase can be regarded as a better choice than OV-1 for the nonpolar phase because it provides better peak shapes for fairly polar compounds such as thiodiglycol and dialkyl alkylphosphonates. Preliminary
identification cannot always be achieved using retention data obtained on one column. When two columns of different polarities are needed, OV-1701 and SE-54 are a good pair, being sufficiently different in selectivity. An OV-1701 column is recommended for use with a sulfur-selective detector, because mustards and their corresponding primary degradation products elute close to each other on an SE-54 column, and identification may be difficult. A polar CW-20M column can be used in only limited applications for the analysis of most polar compounds. Some of the monitored CWC-related chemicals do not elute through this column because of the strong retention and quite low maximum temperature of the phase material. Huber et al. found that theoretically a maximum of about 1 million chemicals can be separated by using a combination of three columns with the stationary phases methyl silicone, 50% phenylmethyl silicone, and methylcyanopropyl silicone.

The ID has a direct influence on retention, efficiency, and capacity of the column. The on-column injection technique requires an ID of at least 0.30 mm. A narrow-bore column with ID of 0.20 mm provides good resolving power with a minimum bleed. It is a good choice for MS analysis as it facilitates a proper adjustment of the carrier gas flow. Narrow-bore columns of limited capacity, however, may be a disadvantage for identification. Columns of ID between 0.25 and 0.33 mm can be considered equal for the separation of treaty-related compounds. Columns of ID 0.53 mm are useful if the sample contains a limited number of chemicals in widely different concentrations.

Thin-film (below 0.20 μm) columns should be avoided because these tend to give poor peak shapes for strongly adsorptive compounds such as thiodiglycol (CAS 111-48-8), dialkyl alkylphosphonates, and aminoalcohols, especially at a low concentration level. Thick-film columns are ideal for the separation of very volatile compounds such as hydrogen cyanide (CAS 74-90-8), phosgene (CAS 75-44-5), and cyanogen chloride (CAS 506-77-4). They are unsuitable, however, for higher molecular-weight compounds such as BZ (CAS 6581-06-2). Standard-film (0.25 – 0.33 μm) thickness offers the best compromise between resolution and sample capacity.

The selection of column length depends on the required resolution and analysis time. Short columns (10 – 25 m) are useful for samples containing a relatively small number of compounds and for screening purposes. To keep the analysis time short and to minimize the adsorption, a 50-m column is useful only for very complex separations requiring maximum resolution. Intermediate column lengths of 25 – 30 m, providing sufficient separation power simultaneously with reasonable analysis time, are in most cases used for the separation of CWC-related chemicals.

### 2.4 Detectors

The critical properties of detectors are sensitivity, selectivity, linearity of response, reproducibility and reliability of operation. Spectrometric detectors, MS and Fourier transform infrared (FTIR), are described in more detail in other sections. The following detectors are useful for the detection of CWC-related chemicals.

The flame ionization detector (FID) is currently the most popular universal detector, having both a wide linear range and great reliability. This detector has been widely used for the detection of CWC-related chemicals. The detection limits for CWC-related chemicals are about 0.1 ng, but the chromatography has a significant influence on the sensitivity: when baseline resolution can be obtained, high sensitivity is the result. In most cases chromatographic interferences are the main problem with the FID. The sensitivity is poor for some compounds such as phosgene (CAS 75-44-5) and hydrogen cyanide (CAS 74-90-8). In addition it is the only detector besides the atomic emission detector (AED) to detect Schedule 2 chemicals pinacolyl alcohol (CAS 464-07-3) and benzilic acid (CAS 76-93-7).

The photoionization detector (PID) is both a universal and a selective detector, with the observed response being dependent on the ionization efficiency of the detected compounds. The PID has a wide linear range of seven orders of magnitude. Any chemical with an ionization potential below 12 eV will give a response. The PID/FID response ratio shows PID to be the more sensitive detector for sulfur-containing CWC-related chemicals such as mustard gas (CAS 505-60-2) and its homologues, for tabun (CAS 77-81-6), and for compounds containing double bonds such as Lewisites. Because no detector gases are needed, the PID may be useful for some on-site applications. However, it is not selective enough for some environmental samples (e.g. air) because of the high response to aromatic compounds.

Despite the great separation power of capillary columns, the analysis at trace level in some matrices may be difficult if only universal detectors are used.

Many selective detectors have been used for monitoring CWC-related chemicals because these chemicals are rich in heteroatoms. In most cases they contain from two to four such as P, S, O, N, Cl, As, and F. Chromatograms are simplified with these detectors and the sensitivity of analysis is increased.

Phosphorus-selective detectors are of greatest importance for verification analysis. The nitrogen–phosphorus detector (NPD) is very sensitive and selective towards compounds containing phosphorus and/or nitrogen, reaching detection limits of about 0.5–5 pg and 10–100 pg respectively. Arsenic-containing compounds such as Lewisites are also detectable with the NPD, but the sensitivity is worse than with the FID. Sensitivity of the NPD depends on the temperature of the NPD bead and can change significantly over time, which must be taken into account in the quantitation. In addition some models of the NPD are not compatible with chlorinated solvents and silylation reagents. The NPD is normally used in the analysis of nerve agents at trace level.

The electron capture detector (ECD) responds to compounds capable of reacting with thermal electrons to form negative ions from halogen-containing chemicals (the order of increasing response is F < Cl < Br < I) and also nitro and α-dicarbonyl groups. In principle the ECD is useful for the analysis of some CWC-related chemicals. Unfortunately, environmental samples usually contain a lot of other ECD active material, which seriously interferes with the identification. The very poor sensitivity of the ECD for fluoridate nerve agents suggests the use of NPD or FPD for these compounds. Also the relatively narrow linear range of the ECD tends to reduce the usefulness of this detector. Several CWC-related chemicals containing chlorine atoms, e.g. vesicants, are detectable with the ECD. Their degradation products are not detected by ECD, so the use of sulfur-selective detectors such as FPD or SCD is recommended for the detection of these compounds due to their better sensitivity and selectivity.

One of the most attractive detectors for screening of CWC-related chemicals is the AED, which is capable of detecting selectively any element below nanogram level. The sensitivity and other properties of the AED are compared to other detectors for a variety of analytes in a number of papers. With this detector it is also possible to determine an approximate empirical formula for unknown compounds. The AED relies on a microwave-induced helium plasma contained in a novel re-entrant cavity with a photodiode array-based optical emission spectrometer. Very-high-purity helium is required as carrier and plasma gas. Leaks are insidious sources of error, especially when oxygen or nitrogen is being measured. The information obtained from the AED is very informative for the unknown chemicals, when the information is collected from various techniques for structure elucidation. Nowadays the AED has been used widely for the detection of CWC-related chemicals.

The usefulness of selective detectors is well demonstrated with the spiked sample analyzed with the FID and selective detectors. Diesel fuel solution (0.03%) containing three CWC-related chemicals at low parts per million level is first analyzed with a FID (Figure 1). It is clear that

Figure 1 Chromatogram recorded with FID (a) from an ethyl acetate solution containing diesel fuel (0.03%), tabun (5 ng), mustard (3 ng), and HN-3 (20 ng); (b) is from a similar solution but with no diesel fuel.
3 IDENTIFICATION METHODS

3.1 Absolute Retention Times

Absolute retention times are, in principle, useful for the identification, but in practice their reproducibility is not very good. Modern gas chromatographs have high precision and retention times within 0.1% or better can be obtained in subsequent runs during the same day. When the analysis is repeated by another instrument the deviation may be several per cent. The reproducibility of absolute retention times is strongly dependent on the proper adjustment of all chromatographic parameters. In addition, the column properties are not exactly the same even when similar columns from the same manufacturer are used. On the other hand, absolute retention times are the most useful identification parameter if only a few compounds are to be monitored and the background is low. This method requires frequent calibration because even small changes in chromatographic conditions will influence the absolute retention times.

3.2 Relative Retention Times

For better reproducibility of retention parameters, relative retention times referenced to a standard compound have been used in several GC applications. The added reference chemical has to be chosen so that it elutes in the middle of the chromatogram. There is always some degree of error in measuring, so that the relative retention times of compounds having short or long retention times might not be very accurate. To obtain better reproducibility it is recommended that several different reference compounds are used for the calculation of relative retention times. However, in this case the use of RIs becomes more attractive. It is a much more reliable approach than the use of absolute or relative retention times, because in RI measurements the retention is measured relative to a homologue series.

3.3 Retention Indices

The reproducibility and reliability of RIs makes it possible to create RI libraries. The reliability and simplicity of index monitoring is increased significantly by using a computer program that searches for the RI pattern, calculates the RIs for all peaks in the chromatogram and then compares the indices with the library data. In addition to the identification of target chemicals, RIs can also be used to locate the interesting peaks between different kinds of GC-based analytical techniques. In this way it is possible to ensure that all GC based techniques used for identification focus on the same peaks even in samples with a complex mixture of chemicals.

The RI system proposed by Kovats was determined at constant temperature using a homologue series of n-alkanes (C-series) for calibration. With mixtures that embrace a wide range of boiling points, several isothermal runs are needed. In these cases, the use of linear RIs is more useful, because this method allows determination of indices for rapidly and slowly eluting compounds in a single analysis. The column temperature is programmed
linearly and the RI of an unknown peak in the chromatogram is calculated from the retention times of the two alkanes eluted on both sides of the compound.\(^{(53)}\)

The distance between each pair of standard peaks is taken as equal, and the linear RIs are calculated by a linear polygon method as shown in Equation (1).

\[
R_{IC} = 100C_n + 100(C_{n+1} - C_n) \frac{t_{RI(x)} - t_{R(n)}}{t_{R(n+i)} - t_{R(n)}}
\]  

(1)

where \(C_n\) and \(C_{n+1}\) are the carbon number of the RI standard eluted before and after the unknown compound, \(t_{RI(x)}\) is the retention time of the unknown compound, and \(t_{R(n)}\) and \(t_{R(n+i)}\) are the retention times of \(C_n\) and \(C_{n+1}\), respectively.

The C-series are the most commonly used RI standards. The RIs of nonpolar substances on nonpolar stationary phases show an almost linear dependence on column temperature. Investigations with other phases and substances suggest, however, that in general the dependence on temperature is not linear but hyperbolic.\(^{(54)}\) The reproducibility of RIs is better if the index standards are structurally similar to the compounds to be analyzed. In the case of polycyclic aromatic hydrocarbons (PAHs) used as standards for other PAHs, the effects of film thickness and temperature programming rate were found to be less than ±0.16 index units. The effect of film thickness using \(n\)-alkanes as standard compounds was under the same conditions between 2.5 and 19.6 index units.\(^{(55)}\)

Nonpolar alkanes are not the most useful as reference standards for most polar CWC-related chemicals. Alkanes, moreover, are not detectable with selective detectors that have to be used for trace analysis. For the specific purpose of identifying CWC-related chemicals, several series of phosphorus-containing retention standards have been synthesized.\(^{(56,57)}\) These standards contain \(n\)-alkane moieties but also phosphorus, sulfur and in most cases fluorine, for easy detection with selective detectors. The most stable and suitable for the analysis of CWC-related chemicals is the M-series, alkyl bis(trifluoromethyl)phosphine sulfides, \((\text{CF}_3)_2\text{P(S)(CH}_2)_n\text{CH}_3\) (where \(n = 2, \ldots, 19\)).\(^{(58)}\)

### 3.3.1 Reproducibility of Retention Indices

The reproducibility of the GC RIs is essential to reliable screening and identification procedure for CWC-related chemicals. The effects of the following parameters on the reproducibility have been evaluated:\(^{(59,60)}\) (1) carrier gas flow rate; (2) starting point of the temperature program; (3) temperature programming rate; (4) injection volume; (5) injection mode; (6) different operator; (7) one- and two-index standard series in the same run; (8) reduced number of index standards; (9) use of external standards; (10) sample solvent; (11) column from the same and different manufacturers; (12) column length; (13) ID of the column; (14) relative peak area compared with the nearest index standard; (15) repeated use of the same column; (16) concentration of the sample; (17) background; (18) multistep temperature program; (19) model of the instrument; and (20) different laboratories. The C- and M-series were used as index standards and the test compounds studied were sarin (CAS 107-44-8), soman (CAS 96-64-0), tabun (CAS 77-81-6), VX (CAS 50782-69-9), mustard gas (CAS 505-60-2), CS (CAS 2698-41-1), CR (CAS 257-07-8), and CN (CAS 532-27-4). A fused-silica capillary column with SE-54 stationary phase was used.

The results of the evaluation showed the RIs to vary only slightly with the operator, different instrument of

c Compound does not elute through column.
the same manufacturer with the same column in one or several laboratories, column individuals of the same manufacturer, solvents (diethyl ether, acetone, and ethyl acetate), use of C- and M-standards alone or together and use of a multistep temperature program. There were no significant differences in the reproducibility of RIs determined using different index standard series. M-standards are relatively nonpolar and differ little in their behavior from C-standards on a nonpolar SE-54 phase. The values of indices also differed when the index standard components were reduced in number. However, the reproducibility remained good. According to this study the external standard method, where retention times of the standards are measured in a separate calibration run, may be used, but this requires very good reproducibility of chromatographic conditions and frequent calibration. The most critical parameters affecting the indices were the carrier gas flow rate, the temperature programming rate, and the properties of the column (e.g. length, ID, and film thickness). The influence was greater at the end of the temperature program than at the beginning. Of the model compounds, VX (CAS 50782-69-9) and the weakly volatile CR (CAS 257-07-8) were more affected by nearly every investigated parameter.

3.3.2 Retention Index Libraries

The application of RIs in the identification of organic compounds has been extensively investigated in two comprehensive reviews. The RIs of some CWC-related chemicals determined against the C-series using on-column injection have been reported. Sokolowski et al. have reported RIs for selected CWC-related chemicals determined against M-series.

A comprehensive RI library was first published by the Finnish Institute for Verification of the CWC. Nowadays the library contains RIs for 145 CWC-related chemicals. RIs have been determined against both M-series and C-series using two different column types (SE-54 and OV-1701: 25 m, 0.32 mm ID and 0.25 μm film thickness). The following chromatographic conditions: carrier gas helium 1.5 mL min⁻¹, splitless injection with splitless time 45 s, temperature program 40 °C (1 min), and heating rate 10 °C min⁻¹ to 280 °C for 10 min. The index values added to the library were the mean values of three measurements. A typical standard deviation for RI values was typically less than 0.5 index units. The correlation between RIs determined using the M-series and the C-series is good and the C-series indices (RI_C) can be calculated from the M-series (RI_M) indices using

\[ \text{RI}_C = 0.9666 \times \text{RI}_M + 487.6. \]

Analysis of all library values for the SE-54 column within M₄-M₂₀ and C₉-C₄₄ (100 compounds) using linear regression gave correlation 0.99991, and the standard deviation of the error between measured and calculated values was 3.5 index units. A collection of RI values of CWC-related chemicals is given in Table 2.

Because the number of CWC-related chemicals is large, a lot of work is needed before all of them are synthesized and reference data recorded. Some indices may be predicted from the previously determined index values. The RI increases for a homolog about 100 index units when a straight carbon chain is lengthened by one CH₂ unit. Thus, for these kinds of homolog the RIs of the long-chain (six or more carbons) family members can be predicted quite accurately from the RI of the family members having three to five or six carbons. The determined and predicted RI values for three different homolog series differed only by 1.3 index units at maximum. In the case of branched-chain esters of alky phosphonofluoridates and their derivatized degradation products the prediction of RIs is more difficult.

For reliable creation of the RI library, all RIs of authentic compounds determined by the Finnish Institute for Verification of the CWC (see Table 2, columns I, II, VI and VIII) are checked against those of special test compounds obtained under the same operating conditions. The RIs of library compounds determined at the beginning and at the end of the library creation must be comparable and consistent. The RI values of test compounds in Table 3 are the mean values recorded during the creation of the RI library by running this test solution after every sixth run. This practice ensures the quality of the library and the analyst can estimate the reliability of the recorded RI values, by running first the test solution and comparing the RI values with those presented in Table 3.

The analysis should be carried out under conditions identical to those used for creating the RI libraries. However, it has been reported that the analytical and column parameters can be changed without altering RIs as long as the initial oven temperature, phase ratio, and the \( r_0/b \) ratio (where \( r_0 \) and \( b \) are the programming rate, dead time, and phase ratio respectively) are kept unchanged. The RI values can be reproduced within few

index units for two columns of different length and ID working under different heating rates with the same or different carrier gas at different gas flow rates.\(^{(74)}\)

## 4 QUALITY CONTROL

According to the recommended operating procedure for the analysis of treaty-related compounds by GC\(^{(22)}\) the solvent blank, sensitivity, and column performance tests should be carried out to check for working and sensitivity of instruments, accuracy of identification parameters, and cross-contamination.

A solvent blank is used to eliminate the possibility of contamination arising from outside the sample, e.g. from the syringe or from the equipment memory effect. It is recommended to use the sample solvent as solvent blank and run this test at the beginning and the end of each sample series and whenever contamination is suspected. The memory effect is possible in the analysis of alkyl phosphoric acids. If the derivatization of these compounds is not quantitative, the nonderivatized acids are adsorbed on the injector glass. The silylation reagent may after this run react in situ on the liner with the adsorbed acids yielding false positive results.

A sensitivity test solution is used to check the sensitivity of the detectors. The test compounds should not adsorb on the column material at low concentration level. It is recommended that test solutions supplied from the instrument manufacturer be used. If these are not available the test compounds presented in Table 4 are suitable for testing the sensitivity of detectors, which are used most often for the detection of CWC-related chemicals.\(^{(22)}\)

The sensitivity test is run after the installation of detectors and columns. It is recommended that the test solution be included in the sample series at least every twentieth sample. The criteria for acceptable detector sensitivity are met if each test compound has a signal-to-noise ratio of 10.

A column performance test is done to ensure the condition of columns and the stability of retention parameters. Because CWC-related chemicals differ greatly from each other, the test compounds have been selected so that their physical, chemical and retention properties on the column are different and so that they elute evenly over the whole chromatogram. Use of the following compounds is recommended: \(d_9\)-dimethyl methylphosphonate, 2,6-dimethylphenol, 5-chloro-2-methylaniline, tri-\(n\)-butylphosphine, dibenzothiophene, malathion, and methyl stearate (Table 3). The concentration of test compounds depends on the sensitivity of detectors. The columns should be tested at quite low concentration level, about 10–50 times above the detection limit. The peak shape of \(d_9\)-dimethyl methylphosphonate can be used to estimate the column activity. The acidic and basic properties of the column can be estimated by comparing the peak heights and areas of phenol and aniline peaks. The same mixture can be used also for quality control in GC/MS to check the tuning and the performance of the instrument by checking the correctness of the mass spectra and the isotope ratios.

Mass spectrometry in combination with gas chromatography (GC/MS) is at present the most suitable technique for the analysis of chemicals related to the Chemical Weapons Convention (CWC), as GC/MS is capable of providing the required analytical evidence needed to sustain any claim of noncompliance under the Convention. Chemical analysis will be carried out on-site, during an inspection using mobile GC/MS equipment, or off-site, in at least two designated laboratories selected by the Organization for the Prohibition of Chemical Weapons (OPCW). GC/MS analysis under the Convention is focused primarily on qualitative analysis (unambiguous identification) rather than on quantitative analysis. Moreover, GC/MS analysis has to be established under a strict quality assurance/quality control (QA/QC) program. The two most applied techniques in verification analysis are low-resolution electron impact (EI) and chemical ionization (CI) GC/MS under full scan conditions. EI is the oldest and still most used ionization technique for the analysis of CWC related chemicals. Therefore, special attention is paid in this article to the fragmentation under EI conditions of a number of chemicals belonging to the CWC Schedule list. The chemicals placed on this list are the target for the verification analysis, especially the Schedule I chemicals, which encompass the well-known chemical warfare (CW) agents such as the nerve agents sarin (GB), soman (GD), tabun (GA) and O-ethyl S-2-diisopropylaminoethyl methylphosphonothiolate (VX) and the vesicants mustard gas (HD) and lewisite (L). Sample preparation methods for these chemicals and their degradation products in environmental, synthetic material, and biological sample matrices are described in this article.

1 INTRODUCTION

Analytical measurements play a role in underpinning the elements of the verification regime of the CWC. It is difficult to conceive of circumstances where any claim of noncompliance under the Convention could be sustained without soundly based analytical evidence. GC/MS is at present the most suitable technique for the analysis of...
The chemicals placed on the CWC Schedule list are the target for the verification analysis, especially the Schedule 1 chemicals, which encompass the well-known CW agents such as the nerve agents GB, GD, GA, and VX and the vesicants HD and L (see Table 1). Incapacitants such as w-chloroaetophenone (code CN, CAS 532-27-4) and o-chlorobenzylidenemalononitrile (code CS, CAS 2698-41-1), which have been developed in the past as military tear gases, are not considered in this contribution. The toxic Schedule 1 chemicals, grouped under Schedule 1.A, consist of a specific number of vesicants and toxins, and several families of compounds. The first family (Schedule 1.A.1) encompasses homologous series of alkyl and cycloalkyl (alkyl/cycloalkyl ≤ C₁₀) alkyl (methyl, ethyl, isopropyl, or propyl)phosphonofluoridates, of which the family of alkyl and cycloalkyl methylphosphonofluoridates is the most important. GB (alkyl : isopropyl) and GD (alkyl : 1,2,2-trimethylpropyl) belong to this family. The trivial name sarin is sometimes used as the reference compound name, for example GF instead of cyclohexyl methylphosphonofluoridate (see Table 1). The second family concerns O-alkyl/cycloalkyl N,N-dialkyl(methyl, ethyl, isopropyl, or propyl)phosphoramidocyanidates (Schedule 1.A.2). These compounds are related to GA (see Table 1). The third family concerns O-alkyl/cycloalkyl (H, ≤ C₁₀) S-2-dialkyl(methyl, ethyl, isopropyl, propyl)aminoethyl alkyl(methyl, ethyl, isopropyl, propyl)phosphonothiolates (Schedule 1.A.3). These compounds are related to VX (see Table 1). In principle, the number of substituent permutations in this family is even greater than in the case of the GB and GA families.

Analysis under the Convention is focused primarily on qualitative analysis (unambiguous identification) rather than on quantitative analysis. For the presence or absence of Schedule 1 chemicals no quantitative limits are set in the Convention. Sample preparation methods for GC/MS proceed with a certain efficiency and for accurate quantitative analysis a determination of the recovery efficiency will be necessary. This may be performed by spiking a blank background sample and carrying out the same sample preparation and GC/MS analysis method on the spiked sample. However, background samples and spiking chemicals are not always available. Moreover, accurate quantitative results are only valid when stable analytes have to be determined, but some CW agents are certainly not stable in environmental samples. Although quantitative analysis may not be the prime aim, sample preparation and GC/MS analysis methods should proceed with sufficient efficiency to allow the determination of the compounds of CW interest at a reasonably low level (e.g. <1 mg kg⁻¹) in environmental samples.

The analysis of scheduled compounds causes several problems owing to the large variety of these compounds. On the CWC Schedule list, very volatile chemicals such as the blood gases hydrogen cyanide (CAS 74-90-8) and phosgene (CAS 75-44-5) are placed along the very polar nonvolatile toxins saxitoxin (CAS 35523-89-8) and ricin (CAS 9009-86-3). In addition to the common organic CHNO-containing compounds, a great variety of other compounds needs to be considered. These encompass organic phosphorus-, sulfur-, arsenic-, chlorine- and fluorne-containing chemicals, some of which are quite reactive and, hence, unstable in environmental matrices.

GF, cyclohexyl sarin; Q, sesquimustard; HN-2, methyl nitrogen mustard; HN-1, ethyl nitrogen mustard; HN-3, nitrogen mustard; DF, methylphosphonyldifluoride; QL, O-ethyl O-2-diisopropylaminomethylphosphonite; PFIB, 1,1,3,3,3-pentafluoro-2-(trifluoromethyl)-1-propene; BZ, 3-quinuclidinyl benzilate; DMMP, dimethyl methylphosphonate; DIMP, diisopropyl methylphosphonate.

It is virtually impossible for all these compounds of interest to the Convention to be determined with the highest efficiency by a few general sample preparation and GC/MS analysis methods. Moreover, saxitoxin and ricin cannot be determined by GC/MS, but require analysis by liquid chromatography (LC) and other mass spectrometric techniques (e.g. electrospray ionization, LC/ES/MS). Depending on the type of inspection, analyses may have to be directed towards the declaration and/or the type of facility. This will be the case, in particular, when biomedical samples have to be considered, resulting from an investigation of alleged use of chemical weapons.

2 ELECTRON IMPACT MASS SPECTROMETRY OF CHEMICAL WEAPONS CONVENTION SCHEDULED COMPOUNDS

2.1 General

EI is the oldest and still most used ionization technique for the analysis of CWC-related chemicals. All major mass spectral data collections consist of EI mass spectra, mostly recorded under accepted standardized conditions such as an ionization voltage of 70 eV, an emission current of 100–200 µA and an ion source temperature

---

**Note:** The table content is extracted from a document discussing the analysis of chemicals related to the Chemical Weapons Convention (CWC) using GC/MS techniques. The table lists various compounds, their systematic and trivial names, CAS numbers, and references to literature. The text mentions the challenges in determining all compounds of interest to the Convention and highlights the use of electron impact mass spectrometry as a primary method.
of 150–200°C. Several types of GC/MS system may be applied, for instance, magnetic sector, quadrupole, or ion trap analyzers. Ion trap systems are considered less applicable, when data comparison is required with spectra from a reference library. In particular, basic compounds related to VX or HN-3s tend to produce protonated molecular ions by self-protonation. Magnetic sector and quadrupole mass spectrometers suffer less interference from self-protonation, and spectra produced with these types of instrument are generally reproducible.

Various classes of CW agents and related compounds have been studied by EI/MS. Research on CW agents normally takes place in specialized chemical defense institutes capable of handling the extremely toxic materials. However, work in this area is sometimes restricted and not all information has been submitted for publication, particularly in the past. EI mass spectra of the most well-known nerve agents were published for the first time in 1979,[2] and a vast number of papers on GC/MS analysis of CW agents and related compounds has appeared in the scientific literature since then. Table 1 refers to the main papers dealing with EI mass spectral data and description of the fragmentation processes of CWC-related chemicals. MS of organophosphorus CW agents was reviewed briefly in 1996 as part of a general review of the chemistry of organophosphorus CW agents.[14] EI mass spectral data on 50 possible precursors for the production of CW agents have been presented in the form of an eight-peak index.[4] Several reports (so-called Blue Books) were published between 1979 and 1986, containing mass spectrometric and gas chromatographic data of compounds of CW interest, by the Finnish Institute for Verification of the CWC (VERIFIN). The compilations, in the form of atlases (available upon request), encompass EI and CI mass spectra of organophosphorus[5] and nonphosphorus CW agents[6] and of some degradation products and precursors of these agents.[7,8] The fragmentation of organophosphorus esters, including a number of possible nerve agent precursors, was extensively reviewed in 1976,[15] EI mass spectra of some simple scheduled chemicals used for the production of CW agents, such as pinacolyl alcohol and thiodiglycol (see Table 1), are found in commercially available mass spectral databases.

The major source for reference data is the OPCW Analytical Database. In principle, this database will contain all essential data for the identification of chemicals relevant to the Convention. Reference data obtained by various analytical techniques need to be compiled. In practice this database will encompass GC retention indices (RIs), EI mass spectra, infrared spectra (IR) and nuclear magnetic resonance (NMR) spectral data in addition to the chemical information data (trivial and International Union of Pure and Applied Chemistry (IUPAC) name, CAS number, Schedule number, structural composition, elemental composition, molecular weight MW). It will be an enormous task to collect analytical data on all chemicals relevant to the Convention as represented in the families containing all possible members of the alkyl/cycloalkyl moiety with up to 10 carbon atoms. Although the database is not complete, it contains the EI mass spectra of most well-known CW agents and their degradation products. The fragmentation under EI conditions of a number of chemicals belonging to the CWC Schedule list will be discussed briefly below.

2.2 Alkyl/Cycloalkyl Alkylphosphonofluoridates

Alkyl/cycloalkyl alkylphosphonofluoridates are generally obtained from an organophosphorus precursor, typically an alklyphosphonic difluoride, and an alcohol. In 1992, over 300 aliphatic and cyclic alcohols were found to be commercially available as fine chemicals, of which inexpensive primary and secondary alcohols are considered suitable for chemical weapons production. By this criterion, approximately 70 alcohols remain of prime interest for the preparation of Schedule 1.A.1 chemicals. Only pinacolyl alcohol, the precursor of GD, is contained in the CWC Schedule list. EI mass spectra have been recorded of the 70 corresponding alkyl/cycloalkyl methylphosphonofluoridates, but not for the corresponding alkyl(ethyl, isopropyl, or propyl)phosphonofluoridates. Most of the mass spectra have been recorded in the 1990s as a contribution to the OPCW Analytical Database.

The EI mass spectra of the alkyl and cycloalkyl esters of methylphosphonofluoridates show particular trends. Apart from the methyl esters, all compounds eliminate an alkene/cycloalkene from the ester group. The main fragmentation of, for instance, methyl methylphosphonofluoridate (CAS 353-88-8) leads towards the base peak at mass to electric charge ratio m/z 82, due to the loss of formaldehyde from the molecular ion (m/z 112). Methyl methylphosphonofluoridate is the only compound in the series of the 70 recorded alkyl/cycloalkyl methylphosphonofluoridates, which produces a molecular ion (int. ca. 5%). All other compounds give rise to the phosphorus-containing ion at m/z 99 ([CH3OF2P]+), which gives either the base peak or is highly abundant.[2,10,16] This ion results from the loss of an alkenyl/cycloalkenyl radical from the molecular ion and is characteristic of the EI mass spectra of GB homologues. In addition to that particular ion, the EI mass spectra show signals due to the alkyl/cycloalkyl moiety or to phosphorus-containing fragments. Typical characteristic low mass ions are m/z 81 ([CH2FOP]+), m/z 65 ([H2O2P]+), m/z 63 ([O2P]+) and m/z 47 ([OP]+). Unfortunately, as the number of carbon atoms in the alkyl/cycloalkyl moiety exceeds six, several of the higher phosphorus-containing and hydrocarbon fragments may
have the same nominal mass (e.g. \( m/z \) 99, 113, 127) and high resolution is required to separate them. As an example, the fragmentation patterns of the nerve agents GB and GD are depicted in Schemes 1 and 2, respectively.

When comparing isomeric \( O \)-alkyl groups, branching has a large effect on the mass spectra. Branched-chain compounds frequently display high-mass fragments in their mass spectra, due to the loss of alkyl radicals (typically: \( m/z \) 111, 125, 139, etc.) or due to the loss of alkenes (typically: \( m/z \) 112, 126, 140, etc.). This is illustrated in Figure 1 by the mass spectra of three different hexyl methylphosphonofluoridates (MW 182), of which the bottom one is from the nerve agent GD. The loss of alkene, in particular, produces information about the branching of the \( O \)-alkyl chain. Branching at the \( \beta \)-position in the \( O \)-alkyl chain leads to an intensive peak at \( m/z \) 112 (see Figure 1a). If the \( O \)-alkyl chain also contains a methyl group at position one, a strong peak at \( m/z \) 126 results (see Figure 1c). When the point of branching is further away from the phosphorus atom, the spectra (see Figure 1b) look more like the spectra of the unbranched homologues. Generally, spectra become less informative when branching is further away from phosphorus, because the phosphorus-containing high-mass fragments have a low abundance (<5%).

The high-mass ions in the EI mass spectra of the cycloalkyl homologues have generally low intensities, because fragmentation of the ester chain cannot occur easily. When the cycloalkyl ring is larger than cycloheptyl or substituted, the mass spectra correspond more to those of the corresponding cycloalkenes. For instance, the mass spectrum of 4-\( t \)-butylcyclohexyl GB corresponds quite well, except for \( m/z \) 99, to that of 4-\( t \)-butylcyclohexene. For an unambiguous identification by GC/MS of these substituted cycloalkyl compounds, additional information in the form of GC retention times or RI and CI data is essential. The fragmentation of the other alkyl and cycloalkyl alkyl(ethyl, isopropyl, or propyl)phosphonofluoridates proceeds, in analogy to that of the GB homologues, with the strong characteristic ions at \( m/z \) 113 (ethylphosphonofluoridates) and \( m/z \) 127 (isopropyl or propyl)phosphonofluoridates instead of \( m/z \) 99. Distinction of the propyl group linked to phosphorus can be made, because the \( n \)-propyl isomer is capable of undergoing the McLafferty rearrangement, whereas the isopropyl isomer is incapable of doing so.

### 2.3 Alkylphosphonochloridates and Alkylphosphonate Diesters

Alkylphosphonochloridates may be used as starting materials for the synthesis of the corresponding alkylphosphonofluoridates. Two of these compounds, chlorosarin and chlorosoman (see Table 1) are placed on the CWC Schedule 1 list. The main peaks in the EI mass spectrum of chlorosarin (MW 156) at \( m/z \) 115/117 (loss of \( C_4H_8 \)) and \( m/z \) 141 (loss of \( CH_3 \)) are in accordance with the fragmentation pattern of GB. The same analogy applies to chlorosoman (MW 198) with abundant ions at \( m/z \) 142/144 (loss of \( C_4H_8 \)) and \( m/z \) 115/117 (loss of \( C_4H_11 \)), and GD. 

Related to the Schedule 1 family of alkyl/cycloalkyl alkylphosphonofluoridates, are two important classes of...
Figure 1 EI mass spectra of (a) 2-methylpentyl, (b) 4-methylpentyl, and (c) 1,2,2-trimethylpropyl methylphosphonofluoridate (GD) recorded at TNO-PML (TNO Prins Maurits Laboratory) on a VG 70-250S GC/MS instrument (Micromass, UK).
compounds. These are the dialkyl/dicycloalkyl alkylphosphonates and the methyl alkyl/cycloalkyl alkylphosphonates, both belonging to the Schedule 2.B.4 chemicals. The first class consists of known impurities of nerve agents and the second class consists of the methyl esters of primarily formed hydrolysis products of nerve agents. DMMP and DIMP (see Table 1) are examples of the first class of compounds and they are frequently used as simulants for nerve agents. These simple esters of methylphosphonic acid were amongst the first phosphorus compounds studied by EI/MS in the early 1960s.[17] The dialkyl esters, including the methyl alkyl esters, fragment by eliminating the alkyl/cycloalkyl group, analogous to alkylphosphonofluoridates. This gives rise to the following characteristic base peaks in the mass spectra:

- m/z 97 dialkyl/dicycloalkyl methylphosphonates
- m/z 111 dialkyl/dicycloalkyl ethylphosphonates
- m/z 125 dialkyl/dicycloalkyl (n- or iso)propylphosphonates
- m/z 111 methyl alkyl/cycloalkyl methylphosphonates
- m/z 125 methyl alkyl/cycloalkyl ethylphosphonates
- m/z 139 methyl alkyl/cycloalkyl (n- or iso)propylphosphonates.

These base peaks are normally accompanied by abundant signals from the subsequent loss of water.

The primary elimination of an alkenyl/cycloalkenyl radical from the molecular ion in the EI mass spectra of dialkyl/dicycloalkyl alkylphosphonates generally gives rise to the most significant high-mass ion, which in turn will lose the second alkene/cycloalkene group towards the above-mentioned base peak ions. The EI mass spectrum of dicyclohexyl methylphosphonate (MW 260, CAS 7040-53-1), for example, produces a peak at m/z 179 ([M – C₆H₁₂]⁺) and the base peak at m/z 97. As with the EI mass spectra of the alkylphosphonofluoridates, information on branching of the O-alkyl chain may be derived from other high-mass fragments.

### 2.4 O-Alkyl/Cycloalkyl N,N-Dialkylphosphoramidocyanidates

GA is the best known example of the family of O-alkyl/cycloalkyl N,N-dialkylphosphoramidocyanidates. Its fragmentation is rather different, compared with that of the alkyl/cycloalkyl methylphosphonofluoridates. Considerable information on GA and its impurities has become available through the GC/MS analysis of munitions-grade GA.[13,18] The smaller phosphoramidocyanidates produce a molecular ion of moderate abundance (m/z 162 in GA is ca. 30%). However, when the O-alkyl chain becomes longer, the intensity of the molecular ion signal decreases or vanishes altogether. The EI mass spectrum of GA is dominated by the dimethylamino group (producing m/z 42, 43, and 44) and a characteristic rearrangement ion produces an intense peak at m/z 70 (see Scheme 3). The rearrangement loss of ethene or ethenyl from the ethoxy group does not occur, but the ethyl group is eliminated instead to produce the m/z 133 ion. In contrast, in the mass spectra of O-alkyl N,N-dimethylphosphoramidocyanidates with longer alkyl chains, the loss of the alkyl radical from the molecular ion leads to a prominent ion or even to the base peak at m/z 135 ([C₃H₈N₂O₂P⁺]). This ion is as characteristic as is m/z 99 for the alkyl/cycloalkyl methylphosphonofluoridates.

![Scheme 3 Fragmentation of GA.](image)

Isomerism of the O-alkyl chain does not influence the spectral intensities as much as with the alkyl/cycloalkyl alkylphosphonofluoridates (see section 2.2). Therefore, only mass spectra of a limited number of compounds need to be compiled to identify faithfully any member of the GA family by comparison with database spectra. There is at the time of writing little or no information available on EI mass spectra of higher N,N-dialkyl(ethyl, isopropyl, or propyl)phosphoramidocyanidates.

### 2.5 O-Alkyl/Cycloalkyl S,2-Dialkylaminoethyl Alkylphosphonothiolates

The EI mass spectra of the O-alkyl/cycloalkyl S,2-dialkylaminoethyl alkylphosphonothiolates are dominated by the S,2-dialkyl(methyl, ethyl, isopropyl, propyl)aminoethyl moieties. This leads for VX to extensive ions at m/z 127, 114, 72, and 30 (see Scheme 4). As for GA, the GC/MS analysis of munitions-grade VX provided a valid source of information.[14] The phosphorus-containing fragments are characteristic (m/z 252, 167, 139), but low in abundance. In the mass spectra of the
2.6 Vesicants

EI mass spectra of HD (see Table 1) and several derivatives, including its main precursor and hydrolysis product thiodiglycol, have been described. The fragmentation of HD follows the same pattern as with other dialkyl sulfides. Cleavage of the bond to the sulfur with charge retention at that atom (thioether cleavage) and cleavage of the C–S bond with charge retention at the chlороalkyl fragment are two major fragmentation routes. With HD (MW 158), this gives rise to the base peak at \( m/z \) 109/111 and an intensive signal at \( m/z \) 63/65 (see Scheme 5). MW information can be obtained for HD and Q (see Table 1, MW 218). However, with an increase in the length in the series of HD homologues, the intensity of the molecular ion decreases. Cleavage of the C–S bond with elimination of the S-CH₂CH₂Cl moiety produces the base peak at \( m/z \) 123/125 in the EI mass spectrum of Q. Other strong peaks are at \( m/z \) 63/65 and \( m/z \) 109/111.

The fragmentation of L 1 (see Table 1) is rather straightforward. A strong molecular ion cluster at \( m/z \) 206 is formed under EI conditions and prominent peaks at high mass values are observed, including a rearrangement towards arsenic trichloride at \( m/z \) 180/182/184 and \( m/z \) 145/147 (see Scheme 6). The cis/trans forms of L 1 have identical EI mass spectra. Technical L consists mainly of the trans isomer. The fragmentation of the three HN-3 gases proceeds in accordance with the basic fragmentation rules for amines (α-cleavage). This results in EI mass spectra with the following base peaks:
• $m/z\ 106/108$ for HN-2 (Cl$_1$, see Table 1, MW 155);
• $m/z\ 120/122$ for HN-1 (Cl$_1$, see Table 1, MW 169);
• $m/z\ 154/156/158$ for HN-3 (Cl$_2$, see Table 1, MW 203).

The molecular ion signals in the mass spectra of the HN-3 gases are weak (<5%) and the peak originating from the 2-chloroethyl group ($m/z\ 63/65$) is rather prominent (>20%).

2.7 Other Chemical Weapons Convention Scheduled Compounds

In addition to chlorosarin and chlorosoman (see section 2.3), there are two families of key precursors placed on the Schedule 1 list. DF (see Table 1) is the best known example of the Schedule 1.B.9 chemicals. The molecular ion, at $m/z\ 100$, gives the base peak in its EI mass spectrum. The fragmentation is somewhat complicated, but gives abundant peaks for the loss of CH$_3$O ($m/z\ 69$) and HF ($m/z\ 80$). The trivalent alkyl/cycloalkyl 2-dialkylaminoethyl alkylphosphonites (Schedule 1.B.10), which are related to the VX family of compounds, have QL (see Table 1) as their main representative because this is the key precursor for the production of VX by a binary process. All main fragments in the mass spectrum of QL can be attributed to the disisopropylaminoethyl group, and none of the eight strongest peaks are phosphorus-containing fragments.$^{(4)}$

In contrast to the vast number of Schedule 1.A chemicals, there are only three toxic chemicals placed under Schedule 2.A of the CWC Schedule list, viz. Amiton, PFIB, and BZ (see Table 1). Amiton (MW 269) produces an EI fragmentation pattern analogous to that of the structurally related VX, with strong peaks originating from the S-2-diethylaminoalkyl moiety ($m/z\ 99, 86, 58$). The molecular ion signal at $m/z\ 269$ is absent; the highest peak of any significance is at $m/z\ 197$ (ca. 1–2%). PFIB (MW 200) produces a molecular ion and peaks typical of fluorine-containing ions ($m/z\ 181$, base peak; $m/z\ 69$, [CF$_3$]$^-$). The compound is extremely volatile and requires special GC conditions (ambient temperature; special columns) in order to be analyzed by GC/MS. The EI mass spectrum of BZ is volatile along with the spectra of a series of other psychoactive glycolates.$^{(12)}$ The spectrum displays a weak molecular ion signal at $m/z\ 337$, and strong peaks arising from the diphenylglycolic ($m/z\ 183$ and 105) and from the quinuclidinyl part ($m/z\ 126$) of the molecule. The same strong peaks at $m/z\ 105$ (benzoylation) and $m/z\ 183$ (loss of COOH) are found in the EI mass spectrum of benzilic acid (MW 228, see Table 1), the key precursor for the production of BZ.$^{(4)}$ Peaks from the second BZ precursor 3-quinuclidinol (MW 127, see Table 1) are observed in the EI mass spectrum of BZ. Although BZ and 3-quinuclidinol can be determined as such by GC/MS, the GC performance is improved significantly after derivatization of the hydroxy group. Benzilic acid cannot be determined as such by GC/MS and conversion into a volatile nonpolar analytical derivative is required.

The Schedule 2 list contains two classes of precursors for the production of GA and its homologues. N,N-Dimethylphosphoramidic dichloride (see Table 1) can be converted to GA with ethanol and a cyanide. Its EI mass spectrum is rather straightforward, with signals due to the molecular ion cluster ($m/z\ 161/163/165$), to the loss of a hydrogen ($m/z\ 160/162/164$) and a chlorine radical ($m/z\ 126/128$), and to the dimethylnitrogen group ($m/z\ 42, 43, 44$). Diethyl N,N-dimethylphosphoramidate (see Table 1) is the best-known example of the second class of possible GA precursors. The compound was also detected as an impurity in munitions-grade GA.$^{(13)}$ The molecular ion ($m/z\ 181$, 15%) fragments by losing an ethyl radical (to $m/z\ 162$), analogous to GA and subsequent elimination of ethene (to $m/z\ 124$). The spectrum base peak, at $m/z\ 44$, is due to the dimethylnitrogen group.

The Schedule 2 list contains three classes of dialkyl-(methyl, ethyl, propyl, and isopropyl)aminoethane compounds, viz. 2-chlorides, 2-ols, and 2-thiols. All three classes are possible precursors of VX and its homologues. In an analogous manner to other simple scheduled chemicals, EI mass spectra are found in commercially available mass spectral databases. Table 1 contains information on the diisopropylaminoethyl compounds. The EI mass spectra of the alcohol (MW 145) and the thiol (MW 161) show the α-cleavage signal at $m/z\ 114$ (base peak), and typical signals for the subsequent elimination of alkenes at $m/z\ 72$ and $m/z\ 30$. In the EI mass spectra of the chloride (MW 163) cleavage takes place preferentially at the N-isopropyl group, giving $m/z\ 148$, and is followed by a loss of propene, resulting in the base peak at $m/z\ 106$.

In addition to the dialkylaminoethane compounds, organophosphorus precursors are needed for the production of Schedule 1.A.3 chemicals. These precursors, such as methylthiophosphonic dichloride (see Table 1), are not specifically mentioned in the Convention text, but they belong to Schedule 2.B.4. The EI mass spectra of the closely related and important precursors, methylphosphonyl dichloride (MW 132) and methylthiophosphonyl dichloride (MW 148), are dominated by the molecular ion cluster and display the base peak signal for [M–Cl]$^+$.$^{15}$ The relatively stronger molecular ion signal in the mass spectrum of the thio compound reflects the larger stability of the ionized molecule. The higher molecular ion signal in EI mass spectra of organothiophosphorus compounds, compared with the corresponding mass spectra of their oxygen analogues, is a general feature.$^{15}$
with EI/MS. Conditions, but by a different mechanism when compared to CI (see Figure 2b). Fragmentation of VX takes place under CI conditions, but by a different mechanism when compared to EI/MS.

Although EI is the most widely used ionization method, there is a clear need for CI data to identify CWC-related compounds. It is clear that there are no reference mass spectra for these Schedule 1 chemicals that can be considered as true physical constants. A compilation of more than one spectrum of the same compound in the OPCW Analytical Database gives an indication of the possible spread.

2.8 Reproducibility of Mass Spectra

Reproducibility of the relative intensities in EI mass spectra is a concern, despite the fact that spectra are recorded under standardized conditions. Different mass spectrometers produce spectra with sometimes large spreads in the relative intensities. An impression of the possible variation is given in Table 2. In this table, the relative intensities of major fragments in the EI mass spectra of three nerve agents, taken from three different sources, are presented. It is clear that there are no reference mass spectra for these Schedule 1 chemicals that can be considered as true physical constants. A compilation of more than one spectrum of the same compound in the OPCW Analytical Database gives an indication of the possible spread.

3 CHEMICAL IONIZATION MASS SPECTROMETRY OF CHEMICAL WEAPONS CONVENTION SCHEDULED COMPOUNDS

Although EI is the most widely used ionization method, there is a clear need for CI data to identify CWC-related chemicals by GC/MS. Extensive fragmentation with resultant loss of MW information is particularly observed in EI mass spectra of the organophosphorus compounds of Schedules 1.A.1 (GB family) and 1.A.3 (VX family). As an example, Figure 2(a) shows the EI mass spectrum of the nerve agent VX. The molecular ion at m/z 267 is absent. Although the pattern of the peaks is characteristic, complete identification is only possible after observation of the pseudomolecular ion at m/z 268 by CI (see Figure 2b). Fragmentation of VX takes place under CI conditions, but by a different mechanism when compared with EI/MS.

Several investigations have been performed on the use of CI in the field of CW agents and related compounds and the influence of the various reagent gases on the selectivity and sensitivity of GC/CI/MS has been described. (12, 19-21) Methane, isobutane, ammonia, ethylene, and methanol have been applied in the formation of CI reagent ions. The first three gases are commonly used for GC/CI/MS of scheduled chemicals and methane CI mass spectra of nerve agents were published in 1979. (12) Among these three gases, ammonia has the lowest proton affinity (PA) and methane has the highest, whereas isobutene (neutral formed from isobutene reactant ions) has an intermediate PA. Therefore, CI with methane generally results in more extensive fragmentation than CI with isobutane or ammonia. In addition ammonia often forms adduct ions [M + NH4]+ with many compounds. The ion source temperature may have an effect on the intensity of the pseudomolecular ions and lower source temperatures are generally favored. The information content of CI mass spectra is typically limited to MW information which is easily accessible from simple calculations. In addition, CI mass spectra vary strongly with CI conditions (choice of gas, etc.) and are more strongly influenced by the instrument used than EI mass spectra. Therefore, compilations of CI/MS data are not as widely used as EI mass spectral databases. Ammonia CI proved to be very useful for the organophosphorus CW agents leading to abundant [M + H]+ and/or [M + NH4]+ pseudomolecular ions. (19) Owing to their relatively low PA, ubiquitously present hydrocarbons will not be ionized, opening up the possibility for more selective detection of other compounds. The difference between using isobutane or ammonia CI for HD and related compounds has been investigated. (20, 21) Both gases provide MW information in the form of either [M + H]+ or [M + NH4]+ peaks, but isobutane lacks the selectivity of ammonia. This was demonstrated by the detection of the HD impurity.
2-chloroethyl (2-chloroethoxy)ethyl sulfide (CAS 114811-38-0) under ammonia CI conditions in the presence of co-eluting hydrocarbons, achieved by ammonia CI but impossible by isobutane CI.\textsuperscript{(21)}

The relatively soft ionization conditions of isobutane and ammonia CI often prevent the observation of fragment ions for identification purposes. This lack of information can be overcome by the use of tandem mass analysis (MS/MS), in which fragmentation can be obtained by collision induced dissociation (CID) of the pseudomolecular ions. Scheduled chemicals have mostly been investigated under positive ion CI conditions, but negative ion CI can be used in principle. However, of the compounds described in section 2 only PFIB
generates negative ions, by electron capture; in this particular case the negative ion CI detection limit lies two orders of magnitude below that observed with EI.

4 SPECIAL GAS CHROMATOGRAPHY/MASS SPECTROMETRY TECHNIQUES

In cases where low detection limits are required, single ion monitoring (SIM) or multiple ion monitoring (MIM) can be applied. Although less specific than full scan MS, a factor of 100–1000 times greater sensitivity may be reached, to allow the detection of scheduled chemicals at low picogram levels per injection. However, for scheduled chemicals with a strong adsorptive nature, such as the nerve agent VX, this low level of detection may not be feasible. The selection of ion masses for SIM or MIM will depend on the compound and the background of the sample matrix, as well as on the GC column, but in general, high and even masses will be more specific. This may not be the case for the alkyl/cycloalkyl alkylphosphonofluoridates, as the masses arising from the organophosphorus moiety under EI conditions coincide with those of ubiquitously present hydrocarbons. In order to be useful for identification, GC/MS(MIM) has to be performed on at least three individual ions of a significant mass spectral (>10% of the base peak) intensity. The GC peaks obtained during the analysis must have coincident maxima, the same peak-width-at-half-height and a signal-to-noise ratio exceeding three. Furthermore, the retention time must agree with that of an authentic reference compound, and the intensity ratio of the selected ion signals should fall within 10% of that of the reference compound. The comparison of the retention time and spectral intensity ratio should be conducted with the same equipment and under the same experimental conditions. By applying high resolution GC/MS with a magnetic sector mass spectrometer, the exact mass of a fragment can be measured, allowing the calculation of the corresponding elemental composition. This provides a valuable tool for the identification of unknowns.

Some fragments in the EI mass spectra of Schedule I chemicals are extremely specific, for example, [CH₃OF₂P]+ (m/z 99.0011) in the spectra of the GB homologues. This ion can easily be distinguished from a possible interfering hydrocarbon background ion [C₆H₁₃]+ (m/z 99.1174), even by the moderate resolution of 5000 (10% valley). High-resolution SIM improves the selectivity and may even allow a higher sensitivity compared with low-resolution SIM, despite the fact that the ion throughput of the instrument is reduced at higher resolution. Detection levels of even less than 1 pg per injection can be reached under optimal conditions.

GC/MS/MS also allows the determination of scheduled chemicals in complex sample matrices with great selectivity and at low detection levels. Information by MS/MS can be obtained either by recording product (parent–daughter) ion spectra of a selected mass or by performing single reaction monitoring (SRM) or multiple reaction monitoring (MRM). In the latter case, a specific fragmentation is monitored, for example by selecting a specific parent ion mass in the first mass analysis step and by transmitting one (SRM) or a few (MRM) formed fragments in the second mass analysis step. Compared with SIM, the selectivity is greatly enhanced.

Several applications of this method have been described in the field of CWC-related chemicals, for instance the determination of small quantities of the nerve agents GB and GD in air contaminated with a huge amount of diesel fuel and sampled on a respirator canister. Reported detection limits for GC/CI/MS/MS(SRM) of ammonium adduct ions were 15 pg for GB (transition m/z 158 to m/z 99) and 80 pg for GD (transition m/z 200 to m/z 183) per injection.²² This shows that the extra dimension of MS/MS adds to the power of GC/MS in the analysis of complex mixtures.

The application of several of the above described GC/MS techniques to real-world samples (clothing, grave debris, soil, and munitions fragments) collected from a Kurdish village in northern Iraq after alleged CW agents attacks in 1992 demonstrates that unequivocal identification can be carried out on different samples with analyte concentrations ranging from low microgram per kilogram to milligram per kilogram level.²³ As an illustrative example, the result of a GC/MS/MS(MRM) analysis of a metal fragment extracted with dichloromethane is depicted in Figure 3. The transition monitored was m/z 125 to m/z 99 and 81 proving the presence of the nerve agent GB.

5 ANALYTICAL DERIVATIZATION FOR GAS CHROMATOGRAPHY/MASS SPECTROMETRY ANALYSIS

Derivatization of analytes may be necessary in order to make them amenable to GC/MS analysis. In most cases of verification analysis, derivatization involves the conversion of polar nonvolatile degradation products of scheduled chemicals into more volatile nonpolar compounds. As polar compounds are normally in an aqueous matrix, this requires the removal of water. This can be accomplished by evaporation to dryness and redissolution of the residue in a suitable organic solvent.
should be taken that polar but nonionic analytes, such as thiodiglycol, do not evaporate. A problem may occur with divalent organophosphorus acids, because they form insoluble salts with metal ions (e.g. Na⁺, K⁺, Mg²⁺, Ca²⁺) present in environmental samples. Removal of the cations with a cation-exchange cartridge before the evaporation to dryness may solve this problem. Contamination of the GC/MS system (injection system, column) may occur, especially with divalent acids such as methylphosphonic acid, in cases where derivatization is incomplete.

There are several derivatization reagents. Most frequently used in verification analysis are the following general reagents:

- **Diazomethane:** this reagent converts acids into methyl esters and is used for the conversion of alkylphosphonic acids into methyl alkylphosphonates. It is one of the most potent methylation reagents. However, it does not methylate the polar alcohols of the CWC Schedule list, for example thiodiglycol.

- **Bis(trimethylsilyl)trifluoroacetamide (BSTFA):** among the many commercially available trimethylsilylation reagents BSTFA is a popular one. It converts acids into trimethylsilyl (TMS) esters and polar alcohols into TMS ethers. However, the TMS derivatives are easily hydrolyzed by traces of water and measurements should proceed directly after derivatization.

- **N-Methyl-N-(tert-butyldimethylsilyl)trifluoroacetamide (MTBSTFA):** this reagent has several advantages above its corresponding TMS analogue, BSTFA. The derivatization occurs readily at room temperature and the derivatives obtained are more stable towards hydrolysis.

Methyl esters of alkylphosphonic acids may also be obtained by heating these acids together with trimethylphenylammonium hydroxide in the hot (e.g. 250°C) injection port of the GC/MS system.

As an example, EI mass spectra of the different derivatives of isopropyl methylphosphonate (CAS 1832-54-8), the primary hydrolysis product of the nerve agent GB, are presented in Figure 4. The EI mass spectra of the methyl alkylphosphonates produce rather characteristic organophosphorus-containing fragments (see section 2.3), which is an advantage over the silylated alkylphosphonates. In contrast, the behavior of ionized silylated alkylphosphonates is dominated by the TMS or TBDMS moieties. An ion at high mass, [M – CH₃]+ and [M – C₆H₅]+, respectively, is usually observed in the EI mass spectra of the TMS and TBDMS esters. Both esters produce the same base peak, at m/z 153, which reflects the elimination of the alkene group (see Figure 4). The base peak or the [M – CH₃]+/[M – C₆H₅]+ ion could be selected for SIM or daughter scan by GC/MS/MS. The three derivatization reactions are routinely carried out in most laboratories, with a slight preference for trimethylsilylation. This preference is reflected in the fact that trimethylsilylation was selected for the OPCW on-site sample preparation methods for GC/MS.

In addition to an increase in the volatility of the analytes, derivatization may also bring about an enhancement in the sensitivity of detection. This is particularly relevant...
Figure 4 EI mass spectra of (a) isopropyl methyl methylphosphonate (MW 152, CAS 690-64-2), (b) isopropyl TMS methylphosphonate (MW 210), and (c) isopropyl tert-butyldimethylsilyl (TBDMS) methylphosphonate (MW 252, CAS 126281-76-3) recorded at TNO-PML on a VG 70-250S GC/MS instrument (Micromass, UK).
with fluorine-containing reagents (perfluorobenzylolation, trifluoroacetylation, heptafluorobutylolation), followed by GC/MS analysis under electron capture negative ion CI conditions.

A special derivatization reaction is required for L1, which is so reactive that it cannot be determined by GC/MS in low quantities (e.g. below 10 ng per injection). It has been known for a long time that L1 reacts with compounds having an α, β-dithiol structure, such as 2,3-dithiopropanol-1 (British-Anti-L; also used for medical treatment). The derivatization reaction can be performed at the analytical level and several examples have been described. The reaction product of L with 3,4-dithiotoluene, 2-(2-chlorovinyl)-5-methyl-1,3,2-benzodithiarsole (see (I)), is a useful derivative for GC/MS analysis.

\[
\text{Cl} - \text{CH} = \text{CH} - \text{As} \left(\begin{array}{c} \text{S} \\ \text{S} \end{array}\right) \text{CH}_3
\]  

(I)

The reaction product of arsenic trichloride (see Table 1) with 3,4-dithiotoluene, 2-chloro-5-methyl-1,3,2-benzodithiarsole, still contains an active chlorine atom, rendering its determination by GC/MS difficult. The derivatization reaction can also be carried out with 2-chlorovinylarsenic oxide (L oxide, CAS 3088-37-7), which is one of the degradation products of L1. Thus, the highly reactive arsenic compounds can be detected as less reactive derivatives amenable to GC/MS.

**6 GAS CHROMATOGRAPHY/MASS SPECTROMETRY ANALYSIS PROCEDURES FOR ENVIRONMENTAL AND SYNTHETIC MATERIAL SAMPLES**

**6.1 General**

GC/MS is the technique best suited to the identification of CW-related compounds. Nanogram amounts of these compounds are conveniently separated by GC and are then used to produce a full mass spectrum. Complex mixtures can be analyzed within hours. The use of GC for the analysis of CW agents in several matrices has been covered, up until 1990, in an extensive review. Although this review focuses on chromatography, frequent mention of GC/MS underlines the popularity of the method.

Several types of GC column with different stationary phases can be used for separation. The most popular columns in verification analysis are fused silica columns (typically 0.2–0.3 mm inner dimension (ID), 25–50 m length) coated with the following phases:

- 100% methyl polysiloxanes (e.g. OV-1™, SE-30™, CPSil5™ or similar commercial phases);
- 95% methyl and 5% phenyl polysiloxane (e.g. SE-54™, DB-5™, CPSil8™ or similar commercial phases);
- 86% methyl, 7% phenyl, 7% cyanopropyl polysiloxane (e.g. OV-1701™, CPSil19™ or similar commercial phases);
- polyethylene glycol (Carbowax™).

Most fused silica columns nowadays show little or no bleeding, resulting in a low MS background. Only the Carbowax™ phase may produce severe bleeding at high temperatures. Normally, fused silica columns are directly inserted into the ion source of the GC/MS instrument, producing a reduced pressure at the end of the column. The temperature of the transfer line is typically maintained at 250 °C, and helium is the preferred mobile phase. The nonpolar stationary phases, in particular SE-54™, are recommended for analyzing samples containing unknown scheduled chemicals. When unknowns have to be analyzed, temperature programming is the preferred option, with a typical program running from 50 to 250 °C at 10 °C min⁻¹. All common GC injectors, such as on-column or splitless injectors, may be used for GC/MS. A retention gap is sometimes used with on-column injections to prevent contamination of the analytical column with material from the sample matrix. Branching of the O-alkyl ester chain of organophosphorus compounds may introduce an asymmetric center, which together with an asymmetric substituted phosphorus atom creates a number of stereoisomers. Diastereoisomers may even be separated on a conventional capillary GC column. This is, for instance, the case with the nerve gas GD. Although this is characteristic for identifying GD, it also increases the GC/MS detection limit by a factor of two.

Below, sample preparation methods of various types of sample will be briefly discussed. As a result of international round-robin exercises in the field of verification analysis a number of recommended operating procedures (ROPs) has been published and tested. Further testing of these procedures has taken place since 1995 during proficiency testing under the auspices of the Technical Secretariat of the OPCW. These procedures were developed for the analysis of samples with unknown analytes, in order to allow the identification of as many different chemicals of CWC interest as possible. This approach implies that these procedures can be further optimized in cases where specific target compounds need to be determined by GC/MS.

Apart from thermodesorption, all other sample preparation techniques are directed towards production of a liquid extract that is subsequently injected into a GC/MS
system. For the simplest of the samples, neat organic liquids or concentrated solutions, the sample preparation method will consist of diluting the sample with a suitable, clean solvent (most often dichloromethane).

6.2 Air Samples

Air samples are normally collected on polymeric adsorbents such as Tenax™ or XAD™. Tenax™ tubes are analyzed in the most efficient way by on-line thermodesorption combined with GC/MS. The technique performs very well for thermostable relatively volatile scheduled compounds such as GB, GD, and HD. High boiling nerve agents such as VX may cause problems due to their highly adsorptive nature. Typical desorption conditions imply heating the adsorption tube to 200 °C for 10 min in a specially designed thermodesorption injector in a helium flow and collecting the desorbed volatile compounds in a preconcentrator (a cold trap or the GC column at subambient temperature).

To overcome problems with VX, a reaction with silver fluoride impregnated on a filter in front of the adsorption tube has been applied. The fluoride converts VX to the more volatile ethyl methylphosphonofluoridate (CAS 673-97-2), which is more amenable to GC. In an alternative approach, adsorption tubes can be extracted with a suitable solvent such as ethyl acetate or acetone (chlorinated solvents may dissolve the polymeric adsorption material). To compensate for the loss of sensitivity, compared with thermodesorption, on-column injection of large volumes, up to 0.5 mL, could be considered. This requires a GC/MS instrument equipped with a solvent vapor exit system, in order to maintain the mass spectrometer vacuum and to prevent contamination of the ion source.

6.3 Synthetic Materials

Scheduled compounds contaminating materials such as rubber, polymers, paint, clothing, charcoal, and concrete are normally extracted with two solvents of different polarity. In the course of an international interlaboratory comparison test, acetone and dichloromethane have been evaluated for the extraction of nonpolar scheduled compounds and water has been evaluated for the extraction of polar degradation products. Sonication for 5–15 min is usually sufficient to obtain good extraction efficiencies. Increasing the surface by cutting or crushing the sample into smaller pieces will enhance the efficiency. The amount of solvent used will depend on the sample, because some samples may absorb relatively large quantities of solvent. As a rule, 1 g of a material needs to be extracted with a few milliliters of a solvent. In general, hydrophobic polymeric materials such as rubber and paint will preserve nerve agents and vesicants to a certain extent. Concrete contains alkaline salts that will hydrolyze nerve agents and vesicants. Therefore, analysis of concrete requires extraction and determination of polar degradation products. This will imply a derivatization step before the GC/MS analysis.

Polymeric material samples contaminated with relatively volatile scheduled compounds such as GB and HD may also be subjected directly to thermodesorption analysis like that employed for air samples. In Figure 5(a), part of the resulting total ion current (TIC) chromatogram of a GC/MS analysis is shown for a rubber material contaminated with diesel fuel and the vesicant HD and its impurity mustard disulfide (CAS 1002-41-1). Despite the complexity of the mixture, the vesicants could be positively identified by extracting pieces of rubber with dichloromethane and subsequent GC/MS analysis of the extract. Polymeric materials, especially rubbers, may contain relatively high (>10%) quantities of additives (e.g. plasticizers), which may interfere with the GC/MS analysis. Better results were obtained after thermodesorption (see Figure 5b), because the collection of the large amount of high boiling hydrocarbons is prevented, with concomitant improvement in the GC performance.

6.4 Preparation of Water Samples

Of the CW agents on the Schedule 1 list, only the nerve agent VX has some stability in water at low pH. Nerve agents of the GB and GA families, and especially vesicants such as HD and L, hydrolyze relatively quickly. Therefore, water samples must be analyzed not only for the scheduled compounds themselves but also for their polar decomposition products (e.g. methylphosphonic acids, thiodiglycol). Some of the hydrolysis products of well-known CW agents, such as GA and L, are unfortunately not placed on the CWC schedule list. Of the possible degradation products of HD, only thiodiglycol is scheduled, whereas 19 sulfur-containing compounds have been identified by GC/MS upon decomposition of munitions-grade HD in water. Although most decomposition products have not been scheduled, the determination of their presence in water provides valuable information about the original presence of scheduled compounds. Water samples can be collected from the environment or from waste tanks at chemical facilities. Measurement and adjustment of the pH with either ammonium hydroxide or HCl will be a necessary step during the sample preparation, especially in the case of waste tank samples.

GC/MS analysis of water samples is frequently preceded by the following sample preparation approaches:

- liquid–liquid extraction with dichloromethane at three different pH values (low, neutral and high)
and subsequently either direct analysis of the organic phase or analytical derivatization of the extract;

- isolation of nonpolar compounds using solid phase extraction (SPE), on a cartridge containing a suitable adsorbent (e.g. C₈, C₁₈-silica or XAD-4), or solid phase microextraction (SPME);

- isolation of alklyphosphonic acids by an ion-exchange column (e.g. SAX™ cartridge) followed by extraction with methanol and, subsequently, derivatization of the extract;

- evaporation to dryness followed by derivatization, with subsequent redissolution of the derivatives.

The sample size will be typically 5–10 mL, although applying SPE or ion exchange sometimes allows the use of larger volumes. For instance, the breakthrough volume of nonpolar analytes such as GD or VX on a conventional C₁₈-silica cartridge is over 100 mL. Among the above-mentioned methods, SPME is relatively new. It combines sample preparation and injection of the sample into one step. Analytes are adsorbed on a polymeric fiber coated with a stationary phase such as polydimethylsiloxane, which is thermally desorbed in the injection port at 250°C. The successful use of the technique for the GC/MS analysis of the nerve agents in water has been described.⁵³ Levels of less than 60 pg mL⁻¹ could be

---

**Figure 5** Part of a TIC chromatogram obtained after the GC/MS analysis of rubber contaminated with diesel fuel and sulfur vesicants. (a) Dichloromethane extract, (b) thermodesorption at 120°C. 1, HD; 2, mustard disulfide. Data recorded at TNO-PML on a VG 70-250S GC/MS instrument (Micromass, UK). (Reproduced from E.R.J. Wils, A.G. Hulst, A.L. de Jong, *J. Chromatogr.*, 625, 382–386 (1992) by permission of Elsevier Science.)
detected under SIM conditions. This shows that SPME provides a valuable addition to the established extraction methods.

6.5 Preparation of Soil and Vegetation Samples

For the purpose of extraction, soil can be considered to be a solid material that may contain relatively large amounts of water (e.g. clay). The sample preparation methods described for solid synthetic materials and water can often be applied prior to the GC/MS analysis. Soil samples are extracted with a nonpolar solvent (e.g. dichloromethane) and a polar solvent (e.g. demineralized water at pH 7). For nitrogen-containing compounds, such as the decomposition products of the nerve agent VX and HN-3s, extraction with water/methanol at pH > 11 is recommended. Alternatively, methanol containing 1% triethylamine may be used as basic extractant. If the soil contains large quantities of water, nonpolar solvents cannot easily penetrate the pores. In those cases, extraction with a solvent that is more miscible with water (e.g. acetonitrile) is often more efficient. Centrifugation and/or filtration to remove small particles will normally be required before the GC/MS analysis is carried out. It is also recommended that the extract be dried (e.g. with sodium sulfate) and that concentration of the extracts be considered when scheduled compounds are not detected.

Pure GC/MS analysis of nonpolar scheduled compounds from soil, is typically preceded by a double extraction of 10 g of the soil sample with 10 mL of dichloromethane (shaking or sonication, during 10 min) and filtration of the combined liquid extracts over a microfilter (0.5–1.0 μm).

Extraction from vegetation may produce complicated sample extracts, because organic plant material (fats, waxes, resins, etc.) will be dissolved as well. Before GC/MS analysis of these samples, a clean-up step is usually performed to remove compounds originating from the matrix. Injection of resins, typically organic acids, could degrade the GC performance dramatically.

7 GAS CHROMATOGRAPHY/MASS SPECTROMETRY ANALYSIS PROCEDURES FOR BIOMEDICAL SAMPLES

During investigations of alleged use of CW agents, samples of biomedical origin may be collected for further analysis in at least two OPCW designated laboratories. The analysis of biomedical samples, such as blood, urine, tissues, and skin, for the presence of scheduled compounds (or their degradation products) generally poses large problems. These problems are due to a lack of knowledge of the fate of most scheduled compounds in biological matrices, usually low concentrations of the scheduled compounds or their metabolites, and interference of the biological matrix. Analysis of biomedical samples still has to be considered as a research, rather than a routine application of GC/MS. In contrast to the situation for environmental samples and synthetic materials, no internationally accepted analysis procedures have been established, neither have the procedures described in literature been validated in international collaborative studies nor has analysis of biomedical samples been the subject of proficiency testing within the context of the CWC. The development of procedures in this field poses the greatest challenge to the analytical chemist. Although GC/MS(ESI) still plays a major role in the analysis of biomedical samples, the role of LC/ES/MS(ESI) is increasing, because this latter method allows direct determination of the mostly polar and, sometimes, high MW metabolites.

Determination of the intact CW agents in urine or blood may proceed by the methods commonly applied to water samples. Extraction with an organic solvent and subsequent clean-up with a Florisil column is a well-established procedure. Rather volatile scheduled compounds can often be successfully recovered and purified from biological materials by means of dynamic headspace stripping and subsequent adsorption on Tenax® tubes; these tubes are then subjected to GC/MS analysis.

After the use of HD in the Iran–Iraq conflict in the 1980s, the fate of HD in animals has been thoroughly investigated and procedures for the analysis of its metabolic decomposition products have been established. Up to 10 metabolites were identified in the urine of the rats, among which were the compounds thiodiglycol and its sulfoxide. The main metabolites 1,1-sulfonylbis[2-(methylsulfinyl)ethane] [O2S(CH2CH2SO2CH2CH2SCH3], 1-methylsulfinyl-2-[2-(methylthio)ethyl-sulfonyl]ethane [CH3SOCH2CH2SO2CH2CH2SCH3], were due to the reaction of HD with glutathione and subsequent conversion of the glutathione adduct by the enzyme β-lyase. Using GC/MS/MS(SRM) a detection limit of 0.1 ng mL−1 urine could be reached, when both compounds were reduced with titanium trichloride to the single analyte 1,1-sulfonylbis[2-(methylthio)ethane] [O2S(CH2CH2SCH3)2]. The hydrolysis products as well as the β-lyase metabolites could be detected in the urine of human victims of HD attacks.

An alternative approach for the analysis of blood samples from the same group of Iranian HD victims has been described. As HD alkylates amino acids in hemoglobin, adducts will be formed which remain in the bloodstream for some time. Selective cleavage of the alkylated N-terminal valine of the α-chain of hemoglobin was carried out by using the modified Edman reagent pentafluorophenyl isothiocyanate. After derivatization of
were thus identified. In four victims of the terrorist attack in the Tokyo subway, both GB hydrolysis products, isopropyl methylphosphonate anions obtained under negative ion CI conditions.

The two hydrolysis products, isopropyl methylphosphonic acids, are prime targets for analyzing metabolites from nerve agents in serum and/or urine. An extremely sensitive procedure involving a number of steps has been developed allowing the detection of femtogram amounts of these acids in serum/urine samples as well in environmental (soil and water) samples. The procedure is based on the isolation and enrichment of the methylphosphonic acids on an ion-exchange cartridge, the conversion to their pentfluorobenzyl esters and CID of the derivatized methylphosphonate anions obtained under negative ion CI conditions. The procedure has not been applied to samples from victims, as yet.

8 ON-SITE GAS CHROMATOGRAPHY/MASS SPECTROMETRY ANALYSIS

On-site GC/MS analysis at a chemical industry or military facility is limited compared with analysis in a well-equipped off-site laboratory. As instruments have to be sent to and installed at an inspected facility, there are requirements with respect to ruggedness, transportability in the field, power consumption, supportability in the field, and ease of operation. Highly sophisticated instruments such as double focusing magnetic sector or triple quadrupole mass spectrometers will certainly not fulfill these requirements. Additional factors for consideration when using on-site analytical techniques are confidentiality of the recorded data, security against possible tampering, compliance with appropriate safety standards, and relatively short setup and analysis times.

GC and MS can fulfill most of the requirements mentioned above. In fact, both methods have been used for years in mobile laboratories for environmental analysis. Relatively small, robust mass spectrometers are commercially available. A well-known example of such an instrument is the so-called MM1 (Bruker-Franzen, Germany). The MM1 instrument has been built into an armored vehicle that is used as a nuclear biological chemical (NBC) reconnaissance system by defense forces of several nations (e.g. Germany, USA). However, a mobile GC/MS combination system equipped with a suitable capillary GC column is required for the on-site analysis of mixtures. Only this technique can provide sufficient information for the different types of sample to be analyzed on-site. Owing to the present state of technology, ruggedized transportable GC/MS instruments have been developed for use in the field with comparable performance to small or bench-top laboratory instruments. The instruments selected in 1996 (EM640S, Bruker-Franzen, Germany and Viking SpectraTrak, Tradeways, USA) for field work during OPCW inspections have only EI capability, limiting the identification possibilities.

The use of GC/MS during an inspection might be conflicting with the confidentiality aspects of the Convention. Therefore, special software and protocols have been developed by OPCW. In order to ensure that sensitive data does not leave an inspection site, the equipment should be configured in such a way that the stored analytical data as well the results of the database comparison can be separated from the instrument and left on-site. Furthermore, the analysis must not allow the identity of compounds which are not subject to the Convention (blinded detection). In practice, this means that no information (gas chromatogram or mass spectrum) obtained from authentic samples will be displayed. A specially designed software package is used to inspect recorded GC/MS data. Library searches (with forward and reverse fitting) are performed on the raw data, using a library restricted to scheduled compounds or to compounds relevant to a particular inspection aim. If necessary, the software can deconvolute GC peaks attributed to suspect compounds from peaks of co-eluting chemicals. A compound name is only displayed when spectrum and RI match factors exceed a preset value. Various controls have been built into the software to reassure proper functioning of the instrument, because analytical data cannot be made visible. Performance checking is carried out.
with regular injection of control samples, to measure RIs (n-alkane series) of analytes and unscheduled reference compounds, and by co-injections of hexachlorobenzene with each extract. In this way, ease of operation, “blinded analysis”, and QA are largely covered by software.

The contents of the OPCW Analytical Database is a key factor in the blinded analysis. The OPCW will base analysis for the presence or absence of chemicals relevant to the Convention on this analytical database. For on-site GC/MS use, a combination of GC and EI data will be required in order to reduce the possibility of false positive identifications.

9 QUALITY ASSURANCE

To guarantee the quality and the security of the samples and the information derived therefrom by analysis, it will be necessary to establish a strict QA/QC program for the GC/MS analysis of chemicals related to the CWC. This program has to be in accordance with an internationally recognized QA system (ISO Guide 25 or equivalent). QA requirements equally apply to on-site analysis in the field and to off-site analysis in OPCW designated laboratories. They encompass the whole chain of events, from taking samples to reporting the analysis of results, with special emphasis on sample preparation and GC/MS analytical methods. Proper coding and sealing of samples and extracts, together with the use of chain of custody forms, is to ensure that a precise history of the samples can be presented. Storage of the samples and extracts in locked refrigerators helps to preserve the samples and to prevent any tampering. Furthermore, frequent checks of the performance of the GC/MS instrumentation and analyses of blank and control samples are required. As the amount of material to be identified decreases, the number of possible errors during the identification process increases. Particularly, when analysis at nanogram or a lower level has to be performed, cross-contamination could be prevented by the application of a strict QA/QC.

For the GC/MS analysis of unknown chemicals, more or less universal procedures have to be used, because of the large variety in matrices and scheduled compounds. This requires the use of ROPs rather than of standard operating procedures (SOPs), because ROPs allow modification of procedures in the process of analysis (validation on the job). However, SOPs have to be followed for instrument calibration and validation.

A key factor in the QA program is the performance control of the instrumentation. A number of test compounds have been recommended to check the performance of a GC/MS instrument for the analysis of scheduled chemicals. These include DMMP-d9, trimethylphosphate, 2,6-dimethylphenol, 5-chloro-2-methylaniline, tri-n-butylphosphate, dibenzothiophene, malathion, and methyl stearate. DMMP is a moderately polar compound and is considered to be a good test compound for checking the GC performance. The deuterated form is recommended because it does not give cross-contamination in the analysis of authentic samples. However, because no scheduled chemicals can be brought on-site during an inspection, the use of DMMP-d9 has been replaced by trimethylphosphate for on-site analysis. The correctness of the intensity ratios in the EI mass spectra can be verified by means of the test compounds with different isotopic peaks: 5-chloro-2-methylaniline (isotope ratio m/z 141/143 should be 33 ± 5%) and dibenzothiophene (isotope ratio m/z 184/186 should be 5.9 ± 1%). In this way sensitivity, GC performance, and mass spectrum quality of the described mixtures (m/z and relative intensity values) can be checked.

ACKNOWLEDGMENTS

The author would like to thank staff members of TNO-PML, Albert Hulst and Ad de Jong for recording the mass spectra presented in this paper, and Dr. Ben van Baar and Dr. Maarten Nieuwenhuizen for providing valuable comments on the manuscript. Dr. Robin Black of the Chemical and Biological Defense Section, Porton Down, UK is acknowledged for providing the results of the GC/MS/MS(MRM) analysis of a metal fragment depicted in Figure 3.

Gas Chromatography/Mass Spectrometry in On-site Analysis of Chemicals Related to the Chemical Weapons Convention

Vesa M.A. Häkkinen
Finnish Institute for Verification of the Chemical Weapons Convention, Helsinki, Finland

1 INTRODUCTION

The convention on the prohibition of the development, production, stockpiling and use of chemical weapons and on their destruction defines strict rules for implementation and verification of it (so called “Verification annex”). The most important means of verification are on-site inspections to various sites defined in the convention.

The convention allows inspection teams during routine inspections to take samples from locations defined in the facility agreement of each inspected site. During challenge inspections and investigations in cases of alleged use of chemical weapons the inspectors may take samples from any location they consider relevant.

Samples taken during inspections are preferably analyzed on-site in laboratories set up by the inspection teams. The equipment and methods of analysis used in the on-site laboratories are tested and approved by the OPCW. The samples taken during on-site inspections are prepared according to standard operating procedures (SOPs) and analyzed by gas chromatography/mass spectrometry (GC/MS). The GC/MS instrument is a specially designed portable system with sophisticated data evaluation software, which is operated in blinded mode in most inspections.

2 GAS CHROMATOGRAPHY/MASS SPECTROMETRY IN ON-SITE INSPECTIONS

2.1 Sample Preparation

Samples taken during inspections are prepared according to SOPs, which are methods specially designed and tested for on-site laboratories. The sample preparation methods, although trying to be as simple as possible, are rather time-consuming requiring several extractions and derivatizations to allow reliable GC/MS analysis of a wide range of chemicals related to the CWC. The detailed descriptions of the sample preparation methods are given elsewhere in this encyclopedia.
2.2 Instrumentation

Several expert groups have thoroughly evaluated all inspection equipment for OPCW, including GC/MS instruments. The demand of portability has been a great challenge for instrument manufacturers, since most existing commercial benchtop instruments were according to the OPCW specifications nonportable. Only two instruments, the American SpectraTrack 672 and the German Bruker EM 640S, fulfilled the specifications of portability. Since the evaluation period the American SpectraTrack 672 instrument has been retired from the market. The German Bruker EM 640S instrument uses a quadrupole mass analyzer and electron impact (EI) ionization. The gas chromatograph is a specially designed, miniaturized device. The Bruker EM640 has a separate gas chromatography (GC) module which is easily mounted on the mass spectrometer. Instead of changing columns, which would be difficult because of the very small size of the equipment, the whole gas chromatograph is changed. Several GC modules may be used for inspection where a large number of samples is expected for analysis. The instrument is operated with a separate ruggedized personal computer (PC). Experts from the OPCW selected the Bruker EM 640S to be used in on-site inspection work.

2.2.1 Bruker EM 640S Mobile Gas Chromatography/ Mass Spectrometry Instrument

The Bruker EM 640S is a ruggedized compact analytical system consisting of the mass spectrometer/GC peripheral modules, a ruggedized PC, and an external power supply.

The mass spectrometer is based on a capillary direct inlet system with a 70 L/s turbomolecular drag pump and an integrated membrane prepump. The only external connections needed are electrical power and helium at a maximum of 2 bar. The ion source is a variable EI source, with 70 eV/200 mA as standard settings, with two changeable filaments. The mass analyzer is an all-glass one-piece quadrupole filter with a dual detector system. The mass range is 1–640 amu with a line width variable from 0.1 amu to 4 amu, the standard line width being 1 amu.

The GC peripherals concept is based on various mass spectrometer inlet and injection modules. The GC modules are directly coupled to the mass spectrometer and modules with different analytical capillary columns can be interchanged with each other. Also the injection system’s split/splitless injector, desorber, automatic air sampler and dual port injector are easily changeable (Figure 1).

The ruggedized PC is designed for use in on-site inspections. It is an Intel-based PC with effective dust protection. The keyboard has an integrated trackball and a touch-screen monitor. The OPCW requirements for data handling and data storage are met by using a removable and exchangeable PC card hard disk and data storage medium. Both storage media may be kept at the inspection site or with the inspection team. After inspection neither the spectrometer nor the data system contains any inspection-related data.

The instrument is packed in four light transport cases with a total weight less than 70 kg. The first case contains the mass spectrometer EM 640S, which is operable in or out of the case. The power input for the instrument is 24 VDC/600 VA. The second case contains the GC periphery and the consumables, including split/splitless injector, GC and gas supply modules mounted on a module plate, electronic module with mounted set of cables, programmable air sampling pump, adsorbent tubes, automatic air sampler module, thermal desorber module, combined injector and thermal desorber module, and a tool kit. The third case contains an external power supply for the EM 640S with a power input of 110–240 VAC, 50–60 Hz/1.5 kVA and a power output of 24 VDC/1 kVA. The fourth case contains the PC, with exchangeable PC card hard disk, magneto-optical drive with write once, read many (WORM) medium, 10-inch touch-screen monitor, and a keyboard with integrated trackball. The power requirement for the PC is 115–230 VAC, 50–60 Hz/3.1 A.

2.2.2 On-site Operational Requirements

The EM 640S GC/MS system is designed for on-site operation and can tolerate a large temperature range, dust, and humidity. Nevertheless, some options/minimum requirements must be taken into consideration. The instrument should be set up in a moderately aired and dry place. A well-ventilated tent in a hot region or a container in a cold region would be sufficient. Direct rain on to the
instrument should be avoided. Dust and humidity are generally no problem for the instrument because of its sealed housing, but dust or sand can damage the fittings of the gas chromatograph. For working place ergonomic reasons, the GC/MS instrument should preferably be set up on, say, a table with enough room for the instrument, analytical tools, and PC.

The power supply for the instrument is 22–30 VDC at an average power consumption of 500 VA, which makes the system operable by batteries. The 24 VDC instrument input power is generated from regular net current voltages by the external power supply. Its power input is variable between 110 and 230 VAC/50–60 Hz at a maximum of 1.4 kVA. The power output is 24 VDC at a maximum of 1 kVA. The PC requires an additional 200 W at 110 or 220 VAC.

The whole instrument configuration requires an overall maximum power of approximately 1 kVA and a generator with 1.2–1.4 kVA electrical power output is sufficient for the on-site operation.

Helium is used as carrier gas with a maximum inlet pressure of 2 bar for the injectors. The average helium consumption per working day is approximately 50 L. This means a 5-L helium bottle at 150 bar keeps the system running for approximately 2 working weeks.

### 2.3 Software for Data Handling

On-site analysis sets special requirements for the data handling. The fear that confidential business information might be revealed when samples are analyzed on-site leads to very special arrangements when evaluating the analytical results obtained during inspections.

The inspectors are not allowed to see the actual raw data to visually investigate the obtained chromatograms and the corresponding mass spectra of a sample taken and analyzed during an inspection. Each set of raw data (a sample run) is analyzed automatically against the library which is preselected for each on-site mission according to the inspection scenario (e.g. to investigate the presence of sarin, its precursors or degradation products on the inspected site).

This so-called blinded software was developed by the National Institute of Standards and Technology (NIST) in cooperation with the OPCW according to the requirements and rules for on-site inspections agreed in the Conference of the State Parties in The Hague. The current, also commercially available, version of this software is called AMDIS.

The AMDIS software produces a standard report from each GC/MS run. The report shows the names of the identified compounds, their retention parameters, and the spectral match factors calculated against the current library. The compounds used for the quality control of the instrument must be included in the library to ensure the correct performance of the instrument during the on-site analysis.

### 2.4 Proposed Standard Operating Procedure for Gas Chromatography/Mass Spectrometry Analysis

The on-site analysis procedure follows the so-called SOP which was specially designed to establish a GC/MS method to provide reliable analytical results in field conditions using blinded software. The analytical procedure has been thoroughly tested with several chemicals related to the CWC to produce reliable and repeatable results at concentration level of 1 mg kg$^{-1}$ or higher.

#### 2.4.1 Standard Gas Chromatography/Mass Spectrometry Conditions

The conditions and operating parameters for the Bruker EM640 instrument are recommended by the instrument manufacturer. Typical EI source conditions are 70 eV electron energy and a source temperature of 150–200 °C. The recommended scanning values (scan range/scan speed) are 40–500 amu/1.0 s.

The standard gas chromatograph operating parameters are as follows:

- column: 95%-dimethyl-5%-diphenylsiloxane (SE-54) stationary phase, 25 m column length, 0.25 mm inner diameter and 0.25 µm film thickness;
- injector port temperature: 250 °C;
- temperature program: 40 °C (1 min) 10 °C min$^{-1}$ to 280 °C (10 min);
- carrier gas: helium;
- carrier gas flow rate: 40 cm s$^{-1}$;
- injection mode: splitless injection, splitless time 1 min;
- injection volume: maximum 1 µL.

Changes in the GC operation parameters can be made if the samples to be analyzed so require. All changes made in the parameters must be carefully documented in the analysis report.
2.4.2 The Sequence for Gas Chromatography/Mass Spectrometry Analysis

The sequence of steps for GC/MS analysis of the samples, each performed under the control of the GC/MS data software is as follows:

1. tune and calibrate the GC/MS instrument (see section 3.1);
2. determine the performance of the GC/MS instrument by analyzing the test mixture by co-injecting it with alkane mixture (see section 3.1);
3. analyze the solvent blank by co-injecting it with 10 ng each of hexachlorobenzene (HCB), 4-bromo-fluorobenzene (BFB), and pyrene (a blank control mixture) (see section 3.3);
4. analyze the sample by co-injecting it with 30 ng each of HCB, BFB, and pyrene (see section 3.4);
5. repeat step 3 if:
   - there is a positive mass spectral match with the OPCW analytical database for a chemical other than from the blank control mixture (see section 3.5);
   - there is a high chemical background (dilute the sample before the new injection);
   - the next sample has a different solvent;
6. repeat step 2 as the last GC/MS measurement or if criteria in section 3.4 are not met.

3 QUALITY CONTROL

3.1 Control of Gas Chromatography/Mass Spectrometry Instrument Performance

Checking instrument performance is essential for the reliability of GC/MS analysis. The relevant aspects to be considered are sensitivity of the method (detection limits), reproducibility of retention indices, and quality of the produced mass spectrometry (MS) data.

The procedure for controlling the performance is divided into two stages:

1. The first stage is automatic tuning and calibration of the GC/MS instrument by using perfluorotributylamine according to the instructions of the instrument manufacturer.
2. The second stage is evaluation of the GC/MS instrument performance by injection of a mixture containing 10 ng of each test chemical (test mixture). The test chemicals are listed in Table 1. As stated, 10 ng of each \( n \)-alkane (\( C_8 - C_{24} \), even numbers, alkane mixture) is co-injected with this test mixture.

</tr>
</tbody>
</table>

The absolute retention times of the \( n \)-alkanes are used to calculate retention indices.

Step 2 must be carried out before and after the analysis of a series of samples or if a malfunction of the GC/MS instrument is indicated.

The chemicals of the test mixture have been selected according to the following criteria:

- to contain no scheduled chemicals of CWC;
- to allow the checking of the adsorption behavior of a GC column for chemicals with different chemical properties; and
- to include chemicals containing the elements chlorine and sulfur, both having a distinctive isotope for checking the correct ionization process of the instrument.

The performance of the GC/MS instrument during the analysis of samples is checked by comparing the measured values of retention index and isotope pattern with reference values for the sample control mixture which is co-injected together with each sample.

3.2 Criteria for Accepting Gas Chromatography/Mass Spectrometry Instrument Performance

The GC/MS instrument is accepted for use if the gas chromatographic and mass spectrometric data produced from at least six of the seven test chemicals determined by the GC/MS data analysis software meet the following requirements:

- The mass spectra of the detected test chemicals have a match value greater than 85 (maximum 100).
The intensity ratios of the isotopic ions are correct. The value is expressed as a percentage of the less abundant isotopic ions relative to the more abundant one ± the acceptable error limits. This means: m/z 143/141 (^37Cl/^35Cl) for 5-chloro-2-methylaniline is 33% ± 5% relative intensity.

The retention indices of the detected test chemicals are within ±20 retention index units of the reference values (the retention indices of the test chemicals are calculated by the GC/MS data software using the absolute retention times of the co-injected n-alkanes).

The signal-to-noise ratio of the chromatographic peak of the detected test chemicals in the total ion chromatogram is greater than five.

### Criteria for Acceptance of Solvent Blank Data

The solvent blank data are accepted if the data for all three co-injected blank control chemicals meet the following requirements:

- Mass spectral match factor is greater than 85;
- Retention indices differ less than ±20 index units from the reference values;
- No positive mass spectral match of other chemicals of the OPCW Analytical Database is made.

If these criteria are not met, repeat section 2.4.2, step 3, and continue from there.

### Criteria for Acceptance of Sample Data

The sample data are accepted if the data for at least two of the three co-injected control chemicals meet the following requirements:

- Mass spectral match factor is greater than 80;
- When the retention index is available, the measured index is within ±40 index units compared with the reference index (actual number to be determined by instrument testing).

If these criteria are not met, repeat section 2.4.2, step 2, and continue from there.

### Criteria for Acceptance of Positive Match with Organization for the Prohibition of Chemical Weapons Analytical Database

Positive match for other than test, control, and retention index chemicals is accepted if all of the following requirements are met:

- Sample data are accepted according to section 3.4;
- Mass spectral match factor is greater than 80;
- When the retention index is available, the measured index is within ±40 index units compared with the reference index (actual number to be determined by instrument testing).

### COMPARISON TO GAS CHROMATOGRAPHY/MASS SPECTROMETRY PERFORMED IN AN OFF-SITE LABORATORY

The only principal difference between the on-site and off-site GC/MS analysis is the access to the raw data. During an on-site inspection the analyst has to rely on the report printed automatically by the AMDIS software. The extensive quality control system created to maintain the correct performance of the on-site instrument should guarantee the correctness and reliability of the analytical result even without access to the actual raw data.

In an off-site laboratory the analyst has the possibility to use his/her own expertise to evaluate the raw data. The obtained total ion or selected ion chromatograms can be viewed to look for co-eluting compounds. The spectra can be printed out and compared visually to library spectra. All relevant data can be annexed in the analytical reports to give the real scientific proof of the existence or nonexistence of any chemical included in each inspection scenario.

Technically the on-site instrument is of high quality. The sensitivity it provides is not far from that of large off-site laboratory instruments. The drawback is the lack of ionization methods other than EI ionization. In many cases the use of chemical ionization is required for measuring the molecular mass of a chemical to improve the reliability of the identification.

### DISCUSSION

The methods for GC/MS in on-site analysis of chemicals related to the CWC were developed by the OPCW in cooperation with NIST and the Finnish Institute for Verification of the CWC (VERIFIN). The instrument manufacturer (Bruker-Franzen Analytik GmbH) also actively participated in this cooperation by developing their instrument to meet the requirements set by the OPCW to solve the difficult analytical task of blinded reliable identification of numerous chemicals with variable chemical and physical properties.

At this time it can be concluded that the laborious project has been successful. The complicated analytical procedure with extensive quality control ensures correct and sensitive instrument performance during the analyses, the NIST AMDIS software provides automatically reliable blinded results from each analyzed sample, and the Bruker EM640S GC/MS instrument has shown its working capabilities in real on-site conditions.

Liquid chromatography/mass spectrometry (LC/MS) is the direct coupling of a chromatographic separation of analytes dissolved in a liquid phase with mass spectrometric detection/identification. Analytes are separated by one or more mechanisms, usually involving hydrophobic, polar or ionic interactions. The components eluting from the LC are introduced directly into the mass spectrometer via an interface, which removes the solvent and ionizes the analyte molecules to produce positive or negative ions. These ions are separated by the mass spectrometer on the basis of their mass-to-charge (m/z) ratios. The recent introduction of versatile and robust interfaces, which use atmospheric pressure ionization (API) (atmospheric pressure chemical ionization (APCI) and electrospray (ES) ionization), has lead to increasing application of LC/MS to the analysis of chemical warfare (CW)-related analytes.

Although LC/MS can be used for the direct analysis of CW agents in aqueous samples, its major application in this field is for the analysis of hydrolysis products of CW agents and other polar degradation products. Reversed phase LC/MS provides a rapid screening procedure for hydrolysis products such as phosphonic acids and thiodiglycol, avoiding the tedious isolation and derivatization required for gas chromatography/mass spectrometry (GC/MS). Increased structural information for unequivocal identification, or improved limits of detection in trace analysis, can be obtained using liquid chromatography/tandem mass spectrometry (LC/MS/MS). LC/MS/MS is also useful for detecting biological markers of poisoning by CW agents in cases where GC/MS is unsuitable.

1 INTRODUCTION

LC/MS is the direct on-line coupling of a chromatographic separation in the liquid phase with mass spectrometric detection/identification. Analytes in a solvent system (the mobile phase) are passed through a chromatography column, packed usually with a solid support coated with a bonded liquid stationary phase. The components are separated by one or more mechanisms, such as hydrophobic, polar or ionic interactions, depending on the nature of the analyte, and mobile and stationary phases. The components eluting from the LC are introduced directly into the mass spectrometer via
an interface, which removes the liquid solvent and ionizes the analyte molecules to produce positive or negative ions. These ions are separated by the mass spectrometer on the basis of their mass to charge (m/z) ratios. A key component of an LC/MS system is the interface between the chromatograph and mass spectrometer, the conditions under which the two operate being mutually incompatible. LC is performed using a large mass flow at or above atmospheric pressure at flow rates in the range 0.1–2 mL min\(^{-1}\), commonly using solvent mixtures such as water–methanol or water–acetonitrile. Mass spectrometric separation of ions occurs under high vacuum. Although LC separation can be performed using normal or reversed-phase mechanisms, as a generalization, those analytes of CW interest that might be separated using normal phase LC are usually analyzed by gas chromatographic methods. LC/MS analysis is most commonly applied to the more polar analytes using reversed-phase conditions.

2 HISTORY

2.1 Liquid Chromatography/Mass Spectrometry Interfaces/Ionization Methods

The four LC/MS interface/ionization systems that have been most widely investigated for the analysis of low molecular mass analytes, such as pesticides and drugs, are thermospray (TS), particle beam (PB) with electron ionization (EI) or chemical ionization (CI), APCI and the related techniques ES and ionspray (IS).\(^{(1-4)}\) A detailed description of these interfaces is given by Niessen and Tinke.\(^{(1)}\)

In the TS interface, nebulization and near complete desolvation occur by transport of the LC eluent through a heated capillary. Ionization occurs by solvent-mediated CI and evaporation processes, the reagent ions being generated from added volatile buffers, such as ammonium acetate, and/or from an auxiliary ionization source such as a filament or discharge electrode. Liquid chromatography/thermospray mass spectrometry (LC/TSMS) operates at typical flow rates of 0.5–1.5 mL min\(^{-1}\). TS is well suited to most low-molecular-weight polar compounds but detection limits can be quite variable; thermally labile compounds may be degraded in the hot capillary and ion currents may fluctuate. Occasional blockage of the TS probe tip by involatile salts may cause operational problems. Because of its commercial availability since the early 1980s, LC/TSMS has been widely used in pesticide analysis,\(^{(2-4)}\) and it was the first LC/MS technique to be applied to the analysis of CW agents\(^{(5)}\) and their degradation products.\(^{(6)}\)

In the PB interface, an almost complete removal of mobile phase constituents occurs by pneumatic or thermal nebulization into a desolvation chamber. A beam of dry particles is then introduced via a momentum separator into the ionization source. PB using EI has the advantage that mass spectra resembling reference EI spectra (as obtained using GC/MS) are produced, but sensitivity for polar analytes is generally lower than with the other techniques and there are limitations to the percentage of aqueous phase that can be accommodated at normal LC flow rates. PB is not the best technique for water-soluble polar compounds.\(^{(7)}\) It has been used rarely in CW analysis although a modification, the eluent jet interface, has been applied to CW-related analytes.\(^{(8)}\)

The API techniques APCI, ES and IS have become accepted as the most robust, sensitive and versatile for the LC/MS analysis of low- and high-molecular-mass polar compounds\(^{(9)}\) they are being increasingly applied to the analysis of polar analytes such as pesticides, drug metabolites, toxins and CW agent degradation products. As the name suggests, these techniques rely on the formation of ions at atmospheric pressure in a source region separated from the high-vacuum mass analyzer, providing practical benefits for coupling to the MS. Both techniques involve nebulization of the liquid eluent from the LC column. With APCI, the LC eluent is introduced into the ion source region via a heated nebulizer assisted by an additional gas flow; ionization is induced usually from a corona discharge and relies on charge transfer in the gas phase, resembling normal CI. ES/IS rely more on liquid-phase chemistry in which an aerosol of highly charged droplets is produced by nebulization in an electric field, followed by desorption of solvated analyte ions from the droplets after vaporization of the solvent. With the IS modification, ES nebulization is combined with pneumatic nebulization, allowing larger LC flow rates to be accommodated. Ionized analyte is transferred from atmospheric pressure to vacuum through a heated capillary and/or skimmer. The literature suggests that APCI is best suited to low-molecular-mass nonionic analytes and ES/IS to ionic and high-molecular-mass materials. APCI can accommodate normal flow rates (up to ~2 mL min\(^{-1}\)) with conventional bore reversed-phase LC systems; modern ES interfaces are usually operated at lower flow rates, <10 µL min\(^{-1}\), and IS at 0.05–0.2 mL min\(^{-1}\). Thermal degradation in the heated nebulizer appears to be much less of a problem with APCI than it is with TS.

TS, APCI and ES/IS are soft ionization techniques, i.e. they impart little excess energy to the molecule in the process of ionization. Under conditions providing optimum sensitivity they usually produce abundant protonated molecules or other adduct ions such as \([M + NH_4]^+\) or \([M + Na]^+\) (quasimolecular ions) with little or no fragmentation. They are therefore good techniques for selective detection and screening, but may
not provide the structural information or fingerprint required for unequivocal identification. One solution is to vary the source conditions to encourage preanalyzer collision-induced dissociation (CID). With TS, greater fragmentation of the molecular ion adducts can be induced by putting more energy into the ions using a discharge ionization or "filament on" technique, and/or by varying the repeller voltages to prolong the residence time of the ions within the source region. With APCI and ES, the ion–molecule collisions can be enhanced by applying a small potential difference between the spray nozzle and skimmer or between the skimmer and an octopole ion guide. With preanalyzer CID, all ions within the source region may be subject to fragmentation. Alternatively, and for optimum signal-to-noise ratio (S/N), CID is obtained using conventional (but instrumentally more expensive) tandem mass spectrometry (MS/MS). In addition to providing structural information, LC/MS/MS is advantageous for improving limit of detections (LODs) in trace analysis (as is GC/MS/MS). Selected reaction monitoring (SRM) of a structurally specific fragmentation is much more selective (in relation to chemical background) than simply monitoring the mass-to-charge ratio for a quasimolecular ion.

The combinations of API sources with benchtop quadrupole mass spectrometers, and more recently with quadrupole ion traps, are now offering LC/MS and LC/MS/MS systems at moderate prices. LC–ion trap instruments offer relatively simple robust LC/(MS)n capabilities and they have the added advantage that full scan MS/MS can be performed without sacrificing sensitivity in comparison with an SRM experiment. Advances in API sources have been reviewed by Niessen.

### 2.2 Liquid Chromatography/Mass Spectrometry

#### Analysis of Chemical Warfare Agents

The major CW agents, included in Schedule 1 of the Annex on Chemicals in the text of the Chemical Weapons Convention (CWC), are the nerve agents, e.g. sarin (GB) [1] [107-44-8], soman (GD) [2] [96-64-0], cyclohexyl sarin (GF) [3] [329-99-7], O-ethyl S-2-diisopropylaminoethyl methylphosphonothiolate (VX) [4] [50782-69-9] and tabun (GA) [5] [77-81-6], the vesicants, e.g. sulfur mustard (H) [505-60-2], nitrogen mustards (7) [51-75-2] and (8) [555-7-1], and Lewisite-1 (9) [541-25-4]; the incapacitant 3-quinuclidinyl benzilate (BZ) [10] [6581-06-2] is included in Schedule 2. Saxitoxin (11) [35523-89-8] and ricin [9009-86-3] are the only examples of toxins included in Schedule 1.

In addition to the established CW agents, Schedule 1 of the CWC includes some analogs of sulfur mustard and defines generic structures (12–14) that encompass thousands of possible nerve agent analogs, where the alkyl substituents on phosphorus or nitrogen (R1, R3) can be C1–C3, and on oxygen (R2) C1–C10.

The nerve agents, mustards and BZ are sufficiently volatile for analysis by GC/MS, although S/Ns with VX and BZ can deteriorate owing to thermal degradation, particularly with dirty injection ports. Capillary GC/MS methodology for CW agents has been well developed since the late 1970s and is usually the method of choice for these compounds. LC/MS analysis of intact CW agents was first reported in 1988 but has generally been used only when the rapid analysis of aqueous samples or extracts is required. An additional factor is that many CW agents react to varying degrees with nucleophilic solvents such as water and methanol, and are usually isolated from aqueous media prior to analysis. The half-lives for GB, GD and VX in water, at typical ambient temperatures and neutral pH, range from 2–3 days to greater than 1 week; sulfur mustard is much less stable, with a half-life of a few minutes, and reversed-phase LC/MS is inappropriate.

As described in section 4.1, LC/MS has been reported for the direct analysis of aqueous solutions of the established nerve agents in water. Nitrogen mustards are
hydrolyzed more slowly than sulfur mustard and analysis by reversed-phase LC/MS has been demonstrated. An example of the use of LC/MS for the identification of BZ in soil is reported in section 4.1.

2.3 Degradation Products of Chemical Warfare Agents

The most important application of LC/MS in CW analysis is for the hydrolysis products of CW agents and other polar degradation products e.g. derived from oxidative and/or hydrolytic decontamination reactions. Polar degradation products are formed in environments and other polar degradation products e.g. derived from analysis is for the hydrolysis products of CW agents. The most important application of LC/MS in CW analysis is for the hydrolysis products of CW agents. For GC/MS analysis they are usually isolated from aqueous media and derivatized to improve their gas chromatographic properties. In most cases they are efficiently extracted from environmental residues with aqueous media and derivatized to improve their gas chromatographic properties. In most cases they are efficiently extracted from environmental residues with the LOD required and on the presence of any interferents. With concentrations of analyte > ca. 100 ng mL\(^{-1}\) direct analysis using selected ion monitoring (SIM) without pretreatment is possible for most analytes and using full mass spectral scanning in favorable cases. In the case of the very polar analytes MPA and ethylphosphonic acid (EPA), which are poorly retained on reversed-phase columns and tend to co-elute with inorganic salts, it may be advantageous to pass the water through a cation-exchange resin, particularly if high concentrations

2.4 Analysis of Toxins of Chemical Warfare Interest

Schedule 1 of the CWC includes only two toxins. These are saxitoxin (11), which has a relatively low molecular mass of 299 (in its nonprotonated form), and ricin which is a complex glycoprotein with a molecular mass of around 62,000 Da. Saxitoxin is of greater concern as a health hazard in seafood (paralytic shellfish poisoning) rather than as a CW agent. It is produced by cold-water dinoflagellates such as Gonyaulax spp. and accumulates in shellfish which feed on these microorganisms. Saxitoxin is a very polar toxin which is protonated at neutral pH and cannot be analyzed by GC/MS. Physicochemical methods for the analysis of saxitoxin have been based mainly on LC or capillary electrophoresis (CE), and methods based on LC/ES/ISMS have appeared. LC/MS has not been reported for ricin although preliminary studies of its ES spectra are being undertaken. LC/ESMS has been reported for another proteinaceous toxin of possible CW interest, staphylococcal enterotoxin B (SEB).

3 SAMPLE PREPARATION

3.1 Water Samples

A major advantage of LC/MS is that aqueous samples can be analyzed with no or minimum sample preparation (other than filtration if necessary), provided that the analyte is present at sufficient concentration. The need for concentration or cleanup of the sample depends on the LOD required and on the presence of any interferents. With concentrations of analyte > ca. 100 ng mL\(^{-1}\) direct analysis using selected ion monitoring (SIM) without pretreatment is possible for most analytes and using full mass spectral scanning in favorable cases. In the case of the very polar analytes MPA and ethylphosphonic acid (EPA), which are poorly retained on reversed-phase columns and tend to co-elute with inorganic salts, it may be advantageous to pass the water through a cation-exchange resin, particularly if high concentrations
of calcium or magnesium ions are present (these bind strongly to these acids). However, this is not recommended as part of the initial screening procedure because other analytes of interest, such as ethanolamines, may be removed.

Simple concentration by evaporation can be used to increase the S/N for the analyte if chemical background is not the limiting factor. Lower LODs can in principle be achieved using various off-line or on-line preconcentration procedures like those used in pesticide analysis.\(^{(19–21)}\)

The majority of the CW analytes of interest with respect to LC/MS are difficult to extract using liquid–liquid extraction. The general trend in the 1990s has been towards the more efficient solid-phase extraction (SPE) on disposable cartridges. SPE cartridges can be used to extract water sample volumes up to about 1 L and the analytes eluted with a small volume of organic solvent (e.g. methanol, acetonitrile). Wils and Hulst\(^{(5)}\) concentrated VX from 50 mL volumes of river water prior to LC/MS, using a C\(_{18}\) SPE cartridge, with subsequent elution with methanol. GB and GD can be similarly concentrated from water samples using C\(_{18}\) cartridges.

For polar analytes with a degree of hydrophobicity, such as alkyl alkylphosphonic acids, C\(_{18}\), C\(_{8}\) or C\(_{2}\) SPE cartridges can be used for extraction provided that the pH is adjusted to around 1 to ensure that the acids are predominantly nonionized.\(^{(22)}\) An alternative is to add a cationic ion-pairing agent such as a tetrabutylammonium salt to enhance extraction onto the lipophilic C\(_{18}\) phase.\(^{(6)}\) Anion exchange provides a second mechanism for concentrating the acids from aqueous extracts and matrices such as urine and serum.\(^{(23,24)}\) Although variable success has been reported.

The most difficult analytes to concentrate from aqueous solution are the small very polar molecules such as MPA, thioglycol sulfoxide and to a lesser degree thioglycol. In the analysis of polar pesticides in water there has been increasing use of polymeric matrices such as polystyrene divinylbenzene and porous graphitic carbon.\(^{(20)}\) These are more retentive for the more polar analytes; polymeric cartridges are showing some promise for the extraction of thioglycol and alkyl alkylphosphonic acids. The most recent technique being applied to the preconcentration of pesticides and CW-related analytes is solid-phase microextraction (SPME).\(^{(25–27)}\) Analytes are partitioned into an immobilized polymeric stationary phase coated onto fused silica fibers. Small volumes (e.g. 10–15 mL) of water sample are required and desorption from the fibers can be achieved directly into a gas chromatograph by thermal desorption or a liquid chromatograph by solvent desorption, using modified inlet systems.

### 3.2 Soil Samples

The ROP for the analysis of soil samples for CW agents and their degradation products involves extraction with dichloromethane, water and methanol–1% triethylamine.\(^{(15)}\) Any further treatment of the aqueous extract depends on factors similar to those discussed above for water samples. The presence of high concentrations of inorganic cations (see above) is the most common problem.

### 3.3 Biomedical Samples

Biomedical samples are generally more complex than environmental ones, and the LODs required to detect biological markers of poisoning (e.g. urinary metabolites) are generally in the region of 1 ppb or lower. LC/MS analysis has rarely been used for the trace level detection of metabolites of CW agents in urine, primarily because lower LODs can be achieved in most cases using GC/MS. The cleanup required depends very much on the particular matrix and the pK\(_a\) of the analyte. Most of the methods described above for the concentration of phosphonic acids in water have been applied to urine prior to GC/MS analysis.\(^{(22,23)}\) Blood is a more difficult matrix and the plasma fraction is usually separated prior to concentration. For the LC/MS analysis of 2-hydroxyethylthioethylhistidine in hemoglobin (see section 5.1.2), a biological marker of sulfur mustard poisoning, the proteinaceous fraction from hemoglobin was digested with hydrochloric acid and the liberated alkylated amino acid concentrated on a cation exchange resin prior to formation of the fluorenylmethoxycarbonyl (Fmoc) derivative.\(^{(28)}\)

### 4 ENVIRONMENTAL APPLICATIONS USING LIQUID CHROMATOGRAPHY/TANDEM MASS SPECTROMETRY AND LIQUID CHROMATOGRAPHY/TANDEM MASS SPECTROMETRY

The need to analyze environmental samples for CW-related chemicals may arise from allegations of CW use, inspections by the Organization for the Prohibition of Chemical Weapons (OPCW) of suspect CW facilities, activities such as the United Nations Special Commission (UNSCOM) missions to Iraq and demilitarization or decontamination activities. ROPs for environmental analysis have been compiled and revised by technical experts following a series of interlaboratory comparison exercises (round robins).\(^{(15)}\) The latter have now been replaced by official proficiency tests organized by the OPCW for those laboratories who wish to become designated for investigations conducted by the OPCW. To
date, all OPCW proficiency tests have involved environmental samples. Many of the more recent developments in analytical methodology have arisen during the course of these round robins and proficiency tests. The focus has been on unequivocal identification of a wide range of scheduled compounds and their degradation products at levels typically around 10 ppm, rather than on the trace analysis of selected analytes at parts per billion levels. Typical environmental samples include soil, water, paint, rubber, plastic, concrete and residues from decontamination processes. Water, soil and decontamination residues are the most likely to contain degradation products and these have been the samples to which LC/MS analysis has most often been applied. The majority of LC/MS applications have employed quadrupole mass spectrometers although the use of ion trap systems is likely to increase.

4.1 Analysis of Chemical Warfare Agents

4.1.1 Liquid Chromatography/Thermospray Mass Spectrometry

LC/TSMS was reported by Wils and Hulst for the analysis of VX, GB, GD and GA in samples such as river water and aqueous soil extracts. The analytes were chromatographed on a C18 column using a mobile phase of methanol or acetonitrile–0.1 M aqueous ammonium acetate. VX gave a good peak shape when chromatographed at a pH close to its pKₐ value (8.5), using a high percentage of organic modifier to obtain an acceptable retention time (ca. 6 min). A problem sometimes encountered when strong solvents are used to elute the more hydrophobic materials under full scanning conditions is co-eluting chemical background. The common plasticizer tri-n-butyl phosphate co-eluted with VX using methanol–0.1 M ammonium acetate (80:20) but resolution was achieved using acetonitrile–methanol–0.25 M ammonium acetate (70:20:10). Because of the range of polarities, GD being considerably more hydrophobic than GB and GA, gradient elution is required to chromatograph the range of nerve agents in a single run.

The TS spectra are dominated by abundant quasi-molecular ions, [M + H]⁺ or [M + NH₄]⁺, depending on whether the proton affinity is less than or greater than that of ammonia. VX has a strongly basic side chain and the TS mass spectrum exhibits an abundant protonated molecular ion; GB, GA and GD possess lower proton affinities than ammonia and their spectra exhibit strong ammonium adduct ions in addition to protonated molecules. The degree of fragmentation observed depends on the mobile phase, the discharge ionization (if any) and repeller voltages. Using a mobile phase of acetonitrile–methanol–0.089 M ammonium acetate (50:43:6), the spectrum of VX exhibited an abundant [M + H]⁺ at m/z 268 with very weak fragment ions at m/z 188 and 146/145. The latter were assigned structures [AcOCH₂CH₂N(i-Pr₂)₂ + H]⁺, [HOCH₂CH₂N(i-Pr₂)₂ + H]⁺ and [H₂NCH₂CH₂N (i-Pr₂)₂ + H]⁺, presumably formed by Michael-type additions of solvent/buffer molecules to the fragment [CH₂==CHN(i-Pr₂)₂ + H]⁺. Increased fragmentation was observed in a mobile phase of 0.1 M ammonium acetate. It is therefore important that similar conditions are used when comparing spectra for confirmatory purposes.

The methodology successfully identified VX in an aqueous extract of soil spiked at 100 ppm as part of a round robin exercise. Preconcentration using a C18 SPE cartridge and SIM enable lower concentrations of VX to be detected. A S/N of 10 was observed using SIM of the protonated molecule after forcing 50 mL of river water spiked at 0.1 ng mL⁻¹ (0.1 ppb) through a C18 cartridge and eluting with 1 mL of methanol.

Wils and Hulst demonstrated that nitrogen mustard, HD-2 could be analyzed in water using LC/TSMS. However, the mustard was converted to a diacetoxyl derivative by reaction with ammonium acetate in the heated interface. A procedure was developed for the determination of HD-2 in the atmosphere after sampling the air onto a silica tube (LOD 1 µg m⁻³, sampling 10 L of air).

4.1.2 Liquid Chromatography/Atmospheric Pressure Chemical Ionization/Mass Spectrometry and Liquid Chromatography/Electrospray/Mass Spectrometry

Few applications of LC/APCI/ESMS have yet been reported for the analysis of intact CW agents, but both techniques should be suitable for the applications described above. APCI and ES can be useful for confirming the molecular mass of V-type agents in proficiency tests as an alternative to GC/CIMS (GC/EIMS gives weak or nonexistent molecular ions, the spectra being dominated by the fragment [CH₂==NR₂⁺] derived from the side chain). Creasy et al. (25) reported the application of LC/APCIMS/MS with SRM to the simultaneous detection of VX and its hydrolysis product EA 2192. (25) (Scheme 1) [73207-98-4] in decontamination solutions. The latter is one of several hydrolysis products of VX (Scheme 1) [73207-98-4] in decontamination solutions.

The latter is one of several hydrolysis products of VX, EA 2192, respectively (Scheme 1).
Thirteen organophosphorus acids consisting of phosphonic acids (26) (hydrolysis products of G and V agents), a thiophosphonic acid (27), plus some phosphoric and thiophosphoric acids (28) (hydrolysis products of pesticides) were resolved or partially resolved on a C18 column. The most polar acids could be chromatographed satisfactorily with 0.1 M aqueous ammonium acetate alone, but the more lipophilic acids (e.g. cyclohexyl methylphosphonic acid (cHexMPA) and pinacolyl methylphosphonic acid (PinMPA) [1932-60-1, 616-52-4]) required methanol–0.1 M aqueous ammonium acetate (30:70). Resolution of thiophosphonic acids from phosphonic acids was improved by lowering the pH of the eluting solvent (from pH 6.8 to pH 5.0), exploiting the lower $pK_a$ values of the former. The use of tetra-$n$-butylammonium hydroxide as ion-pairing reagent was explored to improve the capacity factors which were poor for the more polar acids, but problems were experienced with column degradation, blockage of the TS interface and memory effects.

In positive-ion mode both protonated and ammonium adduct ions are observed in TS spectra, ammonium adducts being the more abundant. The ratio of the quasimolecular ions varies, protonated molecules being weaker with the more polar acids; an increase in vaporizer temperature reduces the $[M+H]^+$/[$M+NH_4]^+$ ratio. PinMPA shows additional ions corresponding to $[CH_3P(O)(OH)_2]$ at $m/z$ 97 and $[CH_3P(O)(OH)_2+NH_4]^+$ at $m/z$ 114; these increase with source temperature. Negative ion spectra are much simpler giving predominantly $[M-H]^-$ ions. LODs were reported in the range 100 pg to 1 ng injected, S/Ns being larger for the acids with smaller alkyl groups R. With the more hydrophobic acids, such as PinMPA and cHexMPA, peak broadening occurs at the longer retention times and the increased methanol content of the eluent reduces the efficiency of the ionization. Water spiked with PinMPA at 50 ng mL$^{-1}$ was at the LOD for this analyte, concentration being required to detect lower concentrations.

Figure 1 Liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry (LC/APCIMS) total ion chromatogram showing the detection of A thiodiglycol and B BZ in a water extract of a spiked soil sample (a), and APCI mass spectrum of BZ (b).

In a recent OPCW proficiency test, APCI proved useful in detecting and identifying BZ spiked into a soil sample at 10 ppm. Figure 1 shows the chromatogram of the water extract of the soil showing the simultaneous detection of the spiked compounds BZ and thiodiglycol.

4.2 Analysis of Chemical Warfare Agent Degradation Products

4.2.1 Liquid Chromatography/Thermospray Mass Spectrometry

LC/TSMS in CW analysis was first applied to the degradation products of nerve agents and to thiodiglycol. In a recent OPCW proficiency test, APCI proved useful in detecting and identifying BZ spiked into a soil sample at 10 ppm. Figure 1 shows the chromatogram of the water extract of the soil showing the simultaneous detection of the spiked compounds BZ and thiodiglycol.

In positive-ion mode both protonated and ammonium adduct ions are observed in TS spectra, ammonium adducts being the more abundant. The ratio of the quasimolecular ions varies, protonated molecules being weaker with the more polar acids; an increase in vaporizer temperature reduces the $[M+NH_4]^+/[M+H]^+$ ratio. PinMPA shows additional ions corresponding to $[CH_3P(O)(OH)_2+H]^+$ at $m/z$ 97 and $[CH_3P(O)(OH)_2+NH_4]^+$ at $m/z$ 114; these increase with source temperature. Negative ion spectra are much simpler giving predominantly $[M-H]^-$ ions. LODs were reported in the range 100 pg to 1 ng injected, S/Ns being larger for the acids with smaller alkyl groups R. With the more hydrophobic acids, such as PinMPA and cHexMPA, peak broadening occurs at the longer retention times and the increased methanol content of the eluent reduces the efficiency of the ionization. Water spiked with PinMPA at 50 ng mL$^{-1}$ was at the LOD for this analyte, concentration being required to detect lower concentrations.

Similar methodology successfully detected PinMPA and the isomeric diisopropyl methylphosphonate in a soil sample analyzed in a round robin exercise. The compounds could be distinguished by retention time and by the $[M+NH_4]^+/[M+H]^+$ ratio, the ammonium adduct being the more intense in the acid. LC/TSMS was among a battery of chromatographic and spectroscopic techniques used to analyze environmental samples collected during the UNSCOM 65 mission to southeast Iraq. No
phosphonic acids were detected but diethyl phosphoric acid and tentatively ethyl phosphoric acid were identified at concentrations in the range 0.1–2 ppm in some water samples. Although these acids could be derived from the hydrolysis of GA, they are also the hydrolysis products of several pesticides.

Tørnes\textsuperscript{(32)} reported the application of LC/TSMS/MS (using a hybrid electrostatic sector magnetic sector quadrupole quadrupole (EBQQ) system) to the analysis of alkyl MPAs (26) \((R = H, \text{Et}, n-\text{Pr}, i-\text{Pr}, \text{pinacolyl})\). CID of the protonated molecules gave a major product ion at \(m/z\) 97, \([\text{MeP(O)(OH)}_2 + \text{H}]^+\), formed from C–O bond cleavage with loss of alkene, plus \(m/z\) 79, \([\text{MeP(O)(OH)}]^+\), from further loss of \(\text{H}_2\text{O}\). Fragment ions originating from the \(O\)-alkyl groups were also observed, e.g. \(m/z\) 85, 57 and 43 from pinacolyl, \(m/z\) 43 and 27 from propyl, providing useful additional structural information. \(n\)-Propyl and isopropyl MPAs gave almost identical MS/MS spectra and could only be reliably distinguished by their different retention times. As a general rule, isomers with \(n\)-alkyl groups are retained more than those with branched chain alkyl groups by the lipophilic \(C_{18}\) stationary phase. Mass chromatograms derived from full scan daughter ion spectra showed a 20–50 times improvement in S/N compared to full scanning LC/TSMS; detection limits were in the region of 0.1 \(\mu\)g mL\(^{-1}\) using this mode of operation.

Thiodiglycol, thiodiglycol sulfoxide and thiodiglycol sulfonyl have been analyzed using LC/TSMS.\textsuperscript{(14,30,33)} Fragmentation pathways are discussed by Munavalli et al.\textsuperscript{(53)} LODs of \(\sim 50\) ng mL\(^{-1}\) were quoted for standards in water, using SIM of the \([M + \text{H}]^+\) and \([M + \text{NH}_4]^+\) ions. The importance of the sulfoxide in the environment was demonstrated by the apparent complete oxidation of thiodiglycol spiked into a soil sample in a round robin exercise.\textsuperscript{(30)}

4.2.2 Liquid Chromatography/Atmospheric Pressure Chemical Ionization/Mass Spectrometry and Liquid Chromatography/Electrospray/Mass Spectrometry

LC/APCIMS and LC/ESMS methods are now superseding those based on LC/TSMS. Black and Read\textsuperscript{(34)} developed a qualitative screening procedure for the simultaneous detection of 19 hydrolysis products derived from nerve agents, sulfur and nitrogen mustards, and BZ, using APCl on a triple stage quadrupole LC/MS/MS instrument. Because of the range of physicochemical properties, i.e. acidic, neutral and basic analytes, varying from very polar (MPA and thiodiglycol sulfoxide) to moderately hydrophobic (PinMPA, benzilic acid), the choice of LC conditions was of necessity a compromise. All 19 analytes chromatographed satisfactorily on a mixed \(C_8/C_{18}\) reversed-phase column, using a water–acetonitrile–0.05% trifluoroacetic acid (TFA) mobile phase and gradient elution. Full or close to baseline resolution was achieved for 14 of the analytes; triethanolamine and \(N\)-methylidethanolamine co-eluted, as did EPA, \(N\)-ethyldethanolamine and thiodiglycol sulfone. However, these can readily be distinguished using mass chromatograms or SIM. A total ion current chromatogram is shown in Figure 2.

Simple alklyphosphonic acids \(R_1^1P(O)(OH)_2\) give abundant \([M + \text{H}]^+\) ions plus adduct ions \([M + \text{CH}_3\text{CN} + \text{H}]^+\). The alkyl alklyphosphonic acids \(R_1^1P(O)(OR)_2\)OH with smaller \(R^2\) groups give \([M + \text{H}]^+\) ions as the base peak plus a strong fragment ion corresponding to \([R_1^1P(O)(OH)]^+\); concentration-dependent dimeric ions \([2M + \text{H}]^+\) are also observed. The \([M + \text{H}]^+\) ions are weaker with \(\text{chMPA}\) and \(\text{PinMPA}\). The intensities of the \([R_1^1P(O)(OH)]^+\) ions increase with the capillary temperature and Q0 offset (source octapole offset voltage). These ions can be utilized for the generic screening of phosphonic acids, by monitoring the selected ions \(m/z\) 97, 111, 125 and so on for alkyl MPA, EPA, and proplyphosphonic acid and so on. Benzilic acid does not give a protonated molecular ion under the conditions used but an abundant ion at \(m/z\) 224, tentatively assigned to \([\text{Ph}_2\text{C} = \text{O} + \text{CH}_3\text{CN}]^+\). Under the conditions employed, all but one of the neutral and basic analytes give APCl spectra containing abundant \([M + \text{H}]^+\) ions with few or no significant fragment ions. Thiodiglycol is the exception, giving an \([M + \text{H} – \text{H}_2\text{O}]^+\) ion as the base peak with a rather weak (\(\sim 7\%\) relative abundance) \([M + \text{H}]^+\). As is the case for TS and ES,
the relative intensities of adduct ions in the spectra are dependent on the mobile phase composition at the time of elution and spectra should be compared with standards run under the same conditions.

LC/MS/MS spectra are used for confirmation of identification. CID spectra obtained from the protonated molecules of phosphonic acids are similar to those obtained using LC/TSMS, although under the collision cell conditions used (triple quadrupole instrument, collision offset −25 V) either none or only weak alkyl fragments are observed with most alkyl alkylphosphonic acids. Hydrolysis products derived from mustards give very good fingerprints under CID conditions. The protonated molecule of 3-quinuclidinol gave very little fragmentation at an increased offset of −35 V, and LC/MS/MS is therefore not appropriate for confirmation.

For lower LODs, a selected ion screening procedure monitoring a total of 14 ions covers the entire range of 19 hydrolysis products. LODs for pure standards were <0.2 ng injected for the hydrolysis products of sulfur and nitrogen mustards, thiodiglycol sulfoxide, diisopropylaminoo ethanol and 3-quinuclidinol, and in the range 0.2–8 ng injected for a series of alkylphosphonic acids and alkyl alkylphosphonic acids, and for benzilic acid. The highest LODs were obtained for MPA and EPA. The methodology was applied to the analysis of aqueous extracts of soil samples collected from bomb craters associated with a CW attack in Iraq. These samples had previously been analyzed by GC/MS and found to contain sulfur mustard, thiodiglycol, isopropyl MPA, MPA and a trace of GB. By searching the mass chromatograms of m/z 105 and 139, derived from full scan LC/APCIMS data, three sulfur-containing compounds in addition to thiodiglycol were detected in an aqueous soil extract (Figure 3). These compounds were identified by LC/MS/MS as thiodiglycol sulfoxide and tentatively as the products HOCH2CH2(SCH2CH2)3OH (29) 1,11-dihydroxy-3,6,9-trithiaundecane (C8H18O2S3) and HOCH2CH2SOCH2CH2SCH2OH (30) 1,8-di-hydroxy-3-oxo-3, 6-dithiaoctane (C6H14O3S12).

LC/ESMS has also been studied for this range of analytes.(35) Using similar LC conditions to those described above, ES was generally more sensitive than APCI for phosphonic acids by a factor of approximately

Figure 3 LC/APCIMS mass and total ion chromatograms showing the detection of A thiodiglycol sulfoxide, B thiodiglycol and C,D additional degradation products derived from sulfur mustard, in a water extract of a soil sample from a bomb crater (a), and CID spectra of thiodiglycol sulfoxide and component C (b). (Reproduced by permission of Elsevier Science from R.M. Black, R.W. Read, J. Chromatogr., A, 759, 79–92 (1997)).
two. A more substantial improvement in sensitivity, up to 10-fold, was obtained by substituting 0.1% formic acid for TFA as the acidic modifier following Zhou and Hamburger’s\(^{(30)}\) demonstration that TFA suppresses and formic acid enhances the formation of \([M + H]^+\) ions for a range of natural products using ES. Using SIM, LODs with 5µL injections were <0.20 ng mL\(^{-1}\), MPA and EPA being at the upper limit. Positive ES was less sensitive than APCI for thiodiglycol sulfoxide.

The ES spectra, like APCI, generally show abundant \([M + H]^+\) ions for the lower alkyl alklyphosphonic acids plus \([RP(O)(OH)_2]^+\) fragment ions. In comparison to APCI spectra, a greater number of adduct ions are observed, particularly \([M + Na]^+\) and \([M + H + MeOH]^+\). Under the conditions used,\(^{(35)}\) the fragment ions \([RP(O)(OH)_2]^+\) were generally more intense than with APCI, probably due to the higher capillary temperature (200°C) required to obtain robust ES in comparison to APCI (150°C). The ready formation of adduct ions with metal ions can be a disadvantage of ES, because the ion current is shared over several quasimolecular ions.

Borrett et al.\(^{(37)}\) reported a detailed study of metal adduct ions formed with phosphonic acids in positive and negative ion ES. These authors applied ES to the direct analysis of aqueous solutions (without LC).\(^{(38)}\) The positive ion ES spectrum of a water solution containing MPA, thiodiglycol and diisopropyl methylphosphonate was complicated by the formation of protonated molecular ions and metal adducts; in contrast, the negative ES gave a much cleaner spectrum dominated by the deprotonated MPA molecule. Negative ion LC/ESMS and LC/APCIMS have been investigated in the authors’ laboratory for the selective detection of phosphonic acids and benzilic acid. Using water–methanol–ammonium acetate buffer. To enhance the structural information, fragmentation was induced by in-source CID, by accelerating the ions in the octapole region of the analyzer, producing intense \([R1P(X)(OH)O]^−\) product ions. Screening for these fragment ions using mass chromatography provided a selective screening procedure, enabling the acids to be detected against a heavy chemical background. The mass of the fragment ions in combination with \([M + H]^+\) tentatively identifies the \(R1\) and \(R2\) alkyl groups present, but does not distinguish isomeric alkyl groups. LODs under full scanning conditions were in the range 20–100 ng mL\(^{-1}\), and 5–25 ng mL\(^{-1}\) using SIM.

Rohrbaugh and Yang\(^{(40)}\) used LC/ESMS to investigate the sulfonium ions formed on prolonged storage and hydrolysis of sulfur mustard. 1-(2-Chloroethyl)-1,4-dithianium ion was identified as the major component in solid mustard heels from large containers.
4.2.3 Atmospheric Pressure Chemical Ionization Versus Electrospray

Work in the authors’ laboratory has been performed on a Finnigan TSQ 700 system and the relative merits of APCI and ES/IS may differ according to the source design. ES was initially regarded as an improvement over APCI for the analysis of phosphonic acids, but experience has shown more variability in comparison to APCI. Greater background has generally been observed using positive ion ES and ion intensities and S/Ns can be quite variable, presumably owing to differing degrees of adduct ion formation according to the background levels of metal ions in the sample. Negative ion APCI also affords cleaner traces than negative ES, with improved S/Ns and limits of detectability in comparison with negative ES. A negative APCI total ion chromatogram (using full scanning) derived from a solution containing a mixture of acidic, basic and neutral hydrolysis products at concentrations of 10 \( \mu \text{g mL}^{-1} \), showing the selective detection of phosphonic acids and benzilic acid, is shown in Figure 5. Using SIM, all of the phosphonic acids were detected at 100 ng mL\(^{-1}\) using 5 \( \mu \text{L} \) injections except for MPA; the latter could be detected at this concentration by using 20 \( \mu \text{L} \) injections. As found with negative ES, S/Ns were particularly good for cHexMPA and PinMPA.

The screening procedure currently employed at CBD uses both positive and negative APCI and a common mobile phase of methanol–water–0.02 M ammonium formate (under gradient conditions). The neutral and basic hydrolysis products are detected at levels similar to those described above in section 4.2.2, although the chromatographic resolution using ammonium formate modifier is not as good as that obtained with TFA. LC/APCIMS provides a rapid and robust screening procedure for aqueous samples and extracts, and has been particularly useful in proficiency tests where time is limited and spiking levels are around 10ppm. Degradation products that have been identified in these tests by LC/APCIMS and LC/APCIMS/MS include MPA, cyclopentyl MPA [73207-99-5], cyclohexyl EPA [170424-87-0], thiodiglycol sulfoxide and N-ethylidethanolamine [139-87-7].

4.2.4 Liquid Chromatography/Particle Beam/Mass Spectrometry

No applications of commercial LC/PB/MS systems to CW analysis have been reported but Kientz et al. have described preliminary results using a related eluent jet interface for combination with micro-LC. The formation of the eluent jet is based on radiofrequency inductive heating. Using flow injection analysis, the EI spectrum of thiodiglycol was found to be comparable to reference EI spectra. The system provided EI-type spectra at levels in the range 1–10ng injected and showed much better linearity of response in comparison to most PB systems. An improved version was reported for obtaining EI and CI spectra. Good results were obtained for 2-diethylaminoethanol [100-37-8], a V agent precursor. Using SIM, 50 pg of 2-diethylaminoethanol could be detected in CI mode.

4.2.5 Liquid Chromatography/Inductively Coupled Plasma Mass Spectrometry (for Lewisite Degradation Products)

Lewisite is hydrolyzed to chlorovinyl arsenous acid [85090-33-1] in environments such as soil, and may be oxidized to chlorovinyl arsenic oxide [3088-37-7]. These analytes are difficult to analyze by LC/MS. LC/ICPMS enables the compounds to be detected as As(III) or As(V), but does not provide a mass spectrum for positive identification. The inductively coupled plasma (ICP) detector is very sensitive, detecting As levels down to 0.1 pg; LODs were <1 ppb.

4.3 Dialkyl Alkylphosphonates

Dialkyl alkylphosphonates are often found as impurities in nerve agents, e.g. diisopropyl methylphosphonate (31) [1445-75-6] in GB and diethyl methylphosphonate (32) [683-08-9] in VX. These diesters are usually more stable in the environment than the CW agents. Dialkyl alkylphosphonates may also be formed in decontamination reactions, e.g. by reactions with ethanol or methoxyethanol present in some decontaminants. They may be present in the aqueous extracts of soil samples and can be identified by LC/MS. The positive APCI and ES spectra of dialkyl alkylphosphonates give intense \([\text{M} + \text{H}]^+\) ions, plus metal or solvent adducts and one or

![Figure 5](image-url)
two low abundance fragment ions, depending on the conditions. With the exception of methyl esters, CID spectra of the protonated molecules are dominated by the product ions arising from sequential neutral losses of alkene, with hydrogen transfer to P—O, to give ions (33) and (34),

\[
\begin{align*}
(31) & \quad \text{R = i-Pr} \\
(32) & \quad \text{R = Et} \\
(33) & \quad \text{R' = CH}_{3}\text{O} \\
(34) & \quad \text{R' = HO'OH}
\end{align*}
\]

e.g. \([M + H – 28]^+\) for ethyl esters, \([M + H – 42]^+\) for propyl esters. These product ions provide a facile means of obtaining a tentative structure for unknowns. Methyl esters fragment by a different pathway, apparently by loss of methanol.\(^{(42)}\) Dialkyl alkylphosphonates are easily distinguished from isomeric alkyl alkylphosphonic acids because they do not give significant responses in negative ion mode.

4.4 Toxins

4.4.1 Saxitoxin

Saxitoxin (11) produces satisfactory spectra with TS, fast atom bombardment (FAB), ES and IS.\(^{(17)}\) Positive IS is very sensitive for saxitoxin (down to 30 pg injected) and gives an abundant \([M + H]^+\) ion. Saxitoxin is usually analyzed as one of several structurally related paralytic shell poisons. The variability in charge states of these toxins creates problems in finding a mobile phase that gives good chromatography and allows efficient IS ionization. Pleasance et al.\(^{(43)}\) reported an LC/ISMS method for the analysis of saxitoxin and related toxins, using a polymeric PRP-1 column with a mobile phase of acetonitrile–5 mM aqueous ammonium acetate and gradient elution. The toxins eluted in order of increasing positive charge, saxitoxin as a rather broad tailing peak with poor reproducibility. Using SIM, a LOD around 0.8–1 µg mL\(^{-1}\) was estimated (1 µL injection). The highly charged toxins are ideally suited to CE separation and CE/MS looks more promising than LC/MS.

4.4.2 Ricin

No LC/MS method has yet been reported for ricin. ESMS of a sample isolated from \textit{Ricinus communis} var \textit{zanzibariensis}, purified by affinity chromatography, contained at least three components with a molecular mass ranging from 62,360 to 63,380 Da.\(^{(44)}\) These probably arise from variations in co- or post-translational glycosylation in the biosynthesis.

4.4.3 Staphylococcal Enterotoxin B

The characterization and LC/ESMS of SEB was reported by Kientz et al.\(^{(18)}\) Chromatography was performed on a microcolumn (600 mm x 0.3 mm ID) with a TSK-gel Phenyl-5PW column packing. The best chromatographic results were obtained using water–acetonitrile gradients with added 0.2% TFA. TFA gave superior peak shape and retention but a four-fold reduction in sensitivity compared to formic acid. SEB could be determined at levels down to 3 pmol mL\(^{-1}\). Additional evidence of identification was obtained using LC/MS/MS of tryptic digests. A typical ES spectrum of SEB is shown in Figure 6.\(^{(44)}\)

5 BIOMEDICAL APPLICATIONS

In the 1990s there has been increased interest in developing forensic methods for the retrospective confirmation of poisoning in victims of chemical attacks. Methods
for the detection of sulfur mustard poisoning are now well developed and some of these rely on LC/MS rather than GC/MS. Methods for the retrospective identification of nerve agent poisoning are still being developed, particularly with regard to blood analysis.

5.1 Biological Markers of Sulfur Mustard Poisoning

Biological markers of sulfur mustard poisoning include urinary metabolites, amino acid residues on the abundant blood protein hemoglobin alkylated with the 2-hydroxyethylthioethyl (HETE) moiety, and similarly alkylated DNA.

5.1.1 Urinary Metabolites

Important urinary metabolites include thiodiglycol sulfoxide (and to a much lesser extent thiodiglycol), conjugates of mustard sulfone with cysteine, e.g. (35), and metabolites formed from the β-lyase pathway, e.g. (36). These metabolites were initially identified by LC/TSMS/MS of fractions separated by semipreparative high-performance liquid chromatography (HPLC), obtained after rats were treated with 35S, 13C4-labelled sulfur mustard. Concentrations in the urine of alleged victims of sulfur mustard poisoning are typically in the range 0.1–100 ppb and detection at the lower limits of this range is difficult to achieve using LC/MS. The bis-sulfone cysteine conjugate (35) was not amenable to GC/MS and an LC/TSMS/MS method was developed based on SRM of the bis-methyl ester, LOD 25 ppb. Thermal instability is a problem with these conjugates and APCI or ES are likely to be superior to TS. The conjugate was not detected in urine samples obtained from casualties of sulfur mustard poisoning (but β-lyase metabolites and thiodiglycol sulfoxide were detected using more sensitive GC/MS methodology).

5.1.2 Alkylated Hemoglobin

Micro-LC/ESMS/MS and LS/ESMS/MS were used to identify the sites of alkylation of hemoglobin by sulfur mustard, by sequencing alkylated peptides detected in tryptic digests of hemoglobin isolated from human blood or hemoglobin treated with sulfur mustard. HETE alkylated N-terminal valine and HETE-histidine (37) were identified as important biological markers.

GC/MS methods were developed for detection of the alkylated valine but problems were experienced in finding thermally stable derivatives for the histidine adduct (37). LC/MS of the underivatized alkylated histidine was possible but the chromatography was poor. Superior LODs were obtained by conversion to the Fmoc derivative (commonly used in liquid chromatography/ultraviolet (LC/UV) analysis of amino acids); the ES spectrum exhibited the protonated molecule as the only significant ion; monitoring the fragmentation [M + H]+ → [CH2CH2SCH2CH2OH]+ (m/z 482 → m/z 105) gave good sensitivity (10 pg injected). The method detected the biological marker in two human subjects who had been exposed to sulfur mustard (Figure 7).

5.1.3 Alkylated DNA

Sulfur mustard alkylates DNA, and N7-HETE-guanine (38) was identified as an alternative biological marker of sulfur mustard poisoning, initially using LC/TS/MS. As found with HETE-histidine, GC/MS analysis was unsatisfactory and an analogous LC/ESMS/MS method was used based on monitoring the reaction [M + H]+ → [CH2CH2SCH2CH2OH]+ (m/z 256 → m/z 105) for its

![Figure 7](image-url)
detection in urine.\(^{(51)}\) The LOD was 0.2 ng mL\(^{-1}\) in urine or 8 pg injected (S/N = 5). The method is also suitable for the determination of the adduct in skin and blood. The adduct was readily detected in the urine of guinea pigs exposed to sulfur mustard.

\section*{6 METHOD DEVELOPMENT}

Development of LC/MS methods requires simultaneous consideration of LC and MS aspects, for example ionization efficiency is affected by mobile-phase composition and flow rate. The following discussion is based on the authors’ experience with the Finnigan API source/interface, although it should be generally applicable to other manufacturers’ interfaces, and to TS/MS. Zhou and Hamburger\(^{(36)}\) have provided a detailed discussion of the parameters to consider when developing screening procedures based on LC/APIMS; Lacorte et al.\(^{(52)}\) reported the effects of temperature and extraction voltages in LC/APCIMS of organophosphorus pesticides; optimization strategies for LC/TSMS have been discussed by Heeremans et al.\(^{(53)}\)

\subsection*{6.1 Liquid Chromatography Aspects}

The majority of LC separations of CWC-related chemicals are performed using reversed-phase conditions on C\(_4\) or C\(_8\) columns. Unlike LC/UV methods, exhaustive optimization of LC conditions is unnecessary owing to the selectivity of MS detection; simple isocratic or, more commonly, linear gradient separations are usually adequate. Modern type B silica packings allow good chromatography of acidic, basic and neutral CW agent degradation products to be obtained using methanol–water or acetonitrile–water mobile phases containing low concentrations of acidic modifiers or volatile buffers. Poor retention of the more polar analytes, such as MPA, is problematic.

The effect on ionization of mobile phase constituents and modifiers needs some consideration. TFA at concentrations \(>\sim 0.05\%\) suppresses ES ionization with consequent reduced sensitivity; formic acid can be used for greater sensitivity. TFA can give better separations, particularly of basic compounds and peptide or amino acid adducts. The use of ammonium acetate or formate buffer allows analyses to be performed in both positive and negative ion modes under similar LC conditions. This is particularly useful for the selective detection of acidic hydrolysis products in screening procedures.

Column dimensions are of lesser importance and internal diameters from 4.6 mm down to capillary have been used. Columns with 2 mm internal diameter appear to be a good compromise. Flow rates of 0.2 mL min\(^{-1}\) are compatible with pneumatically assisted ES or IS without resort to postcolumn splitting; injection volumes of at least 20 µL are possible (though some peak splitting is occasionally observed) and accurate gradients can be delivered by most modern LC pumps. Capillary columns are worth consideration if sample volumes are limited and suitable pumps are available (they are also far more economical with solvents). Column length is dependent on the chromatographic resolution required. Lengths of greater than 150 mm are seldom necessary except for the analysis of complex samples, e.g. protein or peptide digests, where 250 mm columns may be more appropriate.

\subsection*{6.2 Mass Spectrometry Aspects}

The most important MS consideration is the ionization technique. TS is now of lesser importance than the more sensitive and robust API techniques. In our experience, APCI is more suitable for small molecules such as CW-agent hydrolysis products and ES is more suitable for the analysis of more complex biological markers. ES tends to suffer from higher background at low \(m/z\) values than APCI, although this may be dependent on interface design.

Once the ionization technique has been chosen, various parameters need to be optimized for the analysis in question. The main requirement is to achieve efficient ionization and ion transmission. Optimization requires a systematic approach, particularly as some parameters interact. The most important are spray voltage in ES, corona voltage and vaporizer temperature in APCI, capillary temperature and voltage, tube lens voltage and the mobile-phase flow rate and composition. Most of these parameters can be optimized using loop injections, or infusion of analyte into the LC mobile-phase flow, with the assistance of data system software procedures. The effect of capillary temperature on the intensities of the protonated molecules of EMPA, PinMPA and CHexMPA is shown in Figure 8. Optimum intensities are obtained at a temperature around 150 °C; as the temperature is raised towards 200 °C, \([M + H]^+\) decreases and the fragment \([\text{MeP(O)(OH)}_2 + H]^+\) increases.

When a single analyte is of interest, optimization is performed using a structurally significant ion from that compound, usually \([M + H]^+\). For general screening procedures a careful choice of analyte is required. For example, when screening for CW agent hydrolysis products we have found that optimization of interface
parameters to give maximum [M + H]$^+$ (m/z 181) for PinMPA results in conditions giving good sensitivity for all analytes. The main reason for this choice is that of the compounds in our screening procedure, PinMPA has one of the least intense [M + H]$^+$ ions. Similarly, the corresponding [M – H]$^-$ ion (m/z 179) is used for negative-ion mode. Optimization should be carried out at the appropriate mobile phase composition.

Solvent cluster and adduct ions can cause problems in optimization procedures. When using methanol–water mobile phases, particularly with ES at high methanol concentrations, a cluster ion [(MeOH)$_3$ + H]$^+$ is formed. This ion is isobaric with the [MePO(OH)$_2$ + H]$^+$ ion (m/z 97) present in the spectra of all alkyl MPAs and can cause high backgrounds in mass chromatograms of m/z 97. Similarly, when analyzing alkyl MPAs in mobile phases containing acetonitrile, an adduct ion [MePO(OH)$_2$ + H + 2CH$_3$CN]$^+$ is isobaric with [M + H]$^+$ for cHexMPA (m/z 179). Thus, when optimizing MS conditions it is necessary to ensure that a genuine analyte ion is being used and not an interfering cluster, adduct or other background ion that may result in spurious optima being obtained.

The intensity of solvent adduct ions may be reduced by use of a small source octapole offset voltage. Too high a voltage may result in prominent fragment ions due to source CID. Alkali metal adduct ions are not generally prominent in LC/MS, although they may be visible in ES spectra. Ammonium ion adducts are formed with alkyl alklyphosphonic acids when using ammonium acetate or formate as mobile phase modifiers, but are not of great intensity provided modifier concentrations are low. Ammonium adducts are more prominent in the spectra of MPA and EPA, and the neutral analytes thiodiglycol and thiodiglycol sulfone.

6.3 Quality Control

Quality control of screening procedures is performed using analyses of solutions containing a representative mixture of CW-agent hydrolysis products, allowing the quality of both chromatography and mass spectra to be assessed, and determination of LODs. Standard LC column test mixes are not suitable for CW-related analyses as the compounds in these mixes are neither chromatographically nor mass spectrometrically representative of the analytes of interest. In the case of assays for single biological markers, the analysis of standards is required to construct calibration curves and determine detection limits. The use of isotopically labeled internal standards for quantitative analyses is recommended wherever possible.

7 COMPARISON WITH OTHER HYPHENATED TECHNIQUES

7.1 Gas Chromatography/Mass Spectrometry

LC/MS is not used as a substitute for GC/MS in our laboratory but as a complementary technique, mainly for the analysis of polar degradation products. The clear advantage of LC/MS is in the simplicity of sample preparation and speed of analysis. For GC/MS screening procedures, the aqueous extract is concentrated to dryness and the hydrolysis products converted to trimethylsilyl (TMS), tert-butyldimethylsilyl (TBDMS) derivatives, or to methyl esters in the case of phosphonic acids and benzilic acid.\(^{15}\) This is time-consuming and derivatization can result in a large variability in the apparent recovery, particularly in the case of silyl derivatives of alklyphosphonic acids. Problems that can seriously affect derivatization include the presence of large amounts of extraneous organic materials, residual traces of water, and the presence of divalent metal ions such as Ca$^{2+}$ in the case of phosphonic acids. LC/MS allows the very rapid screening of aqueous samples and extracts, provided that analytes are present at concentrations above ca. 0.1–1 µg mL$^{-1}$. It is particularly useful in OPCW proficiency tests where a very large choice of analytes is available from the thousands of possible scheduled compounds and chemical synthesis within a few days may be required for confirmation. Even where samples do have to be concentrated prior to analysis, e.g. using SPE, LC/MS may have advantages because no precautions need to be taken to remove traces of water from the cartridge.
The range of compounds amenable to LC/MS analysis is much broader than with GC/MS. Thus LC/MS can be used to analyze moderately hydrophobic compounds such as VX, very polar compounds such as thiodiglycol sulfoxide, and large molecular mass toxins such as SEB. An additional advantage is that LC/MS and LC/MS/MS spectra are usually very simple, and tentative identification of an unknown may be much easier than for a silylated derivative, where fragmentations can be complex. An example is the additional compounds identified in the soil extract from bomb craters described in section 4.2.

Other useful applications of LC/MS include method development for sample preparation. Recoveries of analytes such as thiodiglycol or thiodiglycol sulfoxide can often be more reliably determined using LC/MS because potential variability due to derivatization is avoided.

On the negative side, the resolution obtainable with capillary gas chromatography columns is superior to that currently obtainable with LC. In terms of sensitivity, and LODs in most matrices, GC/MS is superior. Where trace level analysis is required, e.g. for metabolites such as alkyl alkylphosphonic acids in urine, GC/MS/MS remains the method of choice where suitable derivatives can be found. With more complex biological markers, such as alkylated histidine, thermal instability may prohibit analysis by GC/MS/MS and LC/MS/MS then becomes the method of choice.

### 7.2 Capillary Electrophoresis/Mass Spectrometry

Only one CE/MS method has been reported for CW-agent analysis at the time of writing, although further development is in progress. Kostiainen et al. successfully combined capillary zone electrophoresis (CZE) with IS for the analysis of five nerve agent hydrolys products. The technique provides higher inherent sensitivity and shorter analysis times than LC/MS, but the LODs obtainable are limited by the small injection volumes. CE in combination with less specific detection, e.g. indirect ultraviolet (UV), has been reported for the analysis of phosphonic acids. CE is a good technique for molecules that are ionized in solution, such as phosphonic acids, toxins such as saxitoxin (11), and peptides and proteins, but not for neutral molecules such as thiodiglycol. LC/MS remains the most versatile and broadly applicable method for the screening of aqueous solutions for polar compounds of relevance to the CWC.

Nuclear magnetic resonance (NMR) spectroscopy is a valuable analytical technique for the identification of chemicals related to the Chemical Weapons Convention (CWC). One-dimensional (1-D) proton, carbon, fluorine, and phosphorus NMR spectra (1H, 13C, 19F, 31P) are recorded from test samples for use in the identification of chemicals. The NMR spectrum of a chemical is like a fingerprint. The chemical is identified on the basis of similar sample and reference spectra. In the case of an unknown chemical, two-dimensional (2-D) spectra can assist in its structure elucidation. 2-D NMR is also more suitable than 1-D NMR for the analysis of mixtures.

NMR sample preparation is simple. A liquid sample can be run as such or the liquid is partially or totally changed to a deuterated solvent. Solid samples are extracted with organic or aqueous solvents for the preparation of

Encyclopedia of Analytical Chemistry

analytical samples. The main disadvantage of NMR is the lack of separation methods and the consequent problems of sample background causing occasional resonance overlapping, especially at very low concentrations.

1 INTRODUCTION

NMR spectroscopy is one of the most powerful analytical techniques in organic chemistry for elucidating the molecular structures of chemicals.\(^1\)\(^2\) Moreover, an NMR spectrum may be used like a fingerprint to identify a chemical by comparison with its reference spectrum recorded from the authentic chemical under comparable conditions. The spectrum also reveals information on molecular conformation, isomerism, molecular dynamics, and diastereomers.\(^3\)\(^4\)\(^5\)

During several international interlaboratory comparison (round-robin) and proficiency tests for the verification of chemical disarmament, NMR spectroscopy proved itself to be a useful complementary technique to mass spectrometry (MS) and infrared (IR) spectroscopy.\(^7\)\(^8\)\(^9\)\(^{10}\)\(^{11}\) Test samples included aqueous and organic liquids, soils, sands, concrete, paints, and rubbers spiked with chemicals related to the CWC, usually at levels of about 10 ppm.\(^15\) NMR has also been applied to related field sample analysis.\(^16\)\(^17\)

NMR spectroscopy is applicable to all chemicals dissolving in sufficient amount in a deuterated solvent. Nondeuterated solvents can be used if the experiment is performed unlocked or if a small amount of the corresponding deuterated solvent is added to provide the lock conditions. This article describes the NMR spectroscopic methods used in the analysis of chemical warfare (CW) agents and related chemicals. The flow chart shown in Figure 1 demonstrates the application of NMR spectroscopy to the field of verification of CWC-related chemicals.

The most common nuclei observed are \(^1\)H, \(^{31}\)P, \(^{19}\)F, and \(^{13}\)C. For high concentrations (>1000 ppm) of CWC-related chemicals and low background levels, the \(^1\)H, \(^{13}\)C\(^\text{\text{('}H\text{')}}\), \(^{19}\)F, \(^{31}\)P\(^\text{\text{('}H\text{')}}\), and \(^{31}\)P NMR experiments are all useful for identification. For the analysis of chemicals present in trace amounts (low-ppm level) in environmental samples, the more sensitive \(^1\)H NMR experiment is the method of choice. A 400-MHz spectrometer will generally offer sufficient sensitivity for the detection of chemicals present in trace amounts, although unknown amounts of background may cause problems. The \(^{19}\)F and \(^{31}\)P\(^\text{\text{('}H\text{')}}\) experiments are useful as screening techniques to check for the presence of these nuclei. The acquisition of proton-coupled \(^{31}\)P spectra, which reveal more detailed structural information, is limited more by the poor sensitivity than by background problems. Recording of \(^{13}\)C\(^\text{\text{('}H\text{')}}\) NMR spectra may be futile in concentrations below 100 ppm. In the international tests, the low sensitivity of NMR experiments was compensated in part by concentrating the NMR samples and by running long-term experiments.

Compared with MS and IR spectroscopy, the main problems in NMR experiments are the lower sensitivity and the resonance overlapping caused by large amounts of background chemicals present in the sample.

---

**Figure 1** Verification of CWC-related chemicals by NMR spectroscopy.
Techniques other than NMR are usually hyphenated with gas chromatography (GC) or liquid chromatography (LC) to provide the superior analytical power achieved by combining selectivity and sensitivity. However, the structural specificity of NMR spectra, the capability for the observation of different nuclei, and the 2-D correlation experiments make NMR spectroscopy a valuable technique to be used alongside other techniques. With regard to the chemicals listed in the Schedules of the CWC, NMR spectroscopy is particularly useful for the analysis of alkylphosphonates (e.g. precursors or degradation products of nerve agents), thioalcohols, and amino alcohols and their salts, but it is not limited to these.

2 INSTRUMENTS AND EQUIPMENT

2.1 Spectrometer

The following are recommendations for an NMR spectrometer suitable for the analysis of CWC-related chemicals:

- capability for observing $^1$H, $^{13}$C, $^{19}$F, and $^{31}$P nuclei (recording $^1$H, $^{13}$C,$^1$H, $^{19}$F, $^{31}$P$^1$H, and $^{31}$P NMR spectra);
- a proton resonance frequency preferably of 200 MHz or more;
- capability for control of the sample temperature to an accuracy of within $\pm 0.5\, ^\circ C$;
- a data system adequate for acquisition, processing, printing, and storage of all necessary data.

Modern computerized high-field NMR spectrometers normally fulfill these requirements and, in addition, are routinely capable of running the latest pulse sequences to record the multidimensional spectra useful for structure elucidation of unknown chemicals. The higher the resonance frequency is, the smaller the amount of a chemical needed for its identification. Higher-frequency instruments also provide larger resonance dispersion, which simplifies the spectra and helps in their analysis. In interlaboratory comparison/proficiency tests, the proton frequencies have ranged from 250 to 600 MHz, but even the lower-frequency instruments have produced useful spectra. Temperature control is recommended because line broadening may occur with a drift in temperature – an effect that may be particularly important during long-term accumulations.

2.2 Probe Heads

The capability of recording the spectra of different nuclei depends on the probe head. $^1$H, $^{13}$C, $^{19}$F, and $^{31}$P nuclei are observed in verifying CWC-related chemicals and the probe head is selected accordingly. The most common probe head diameters are 5 and 10 mm. For the same sample concentration a 10-mm probe head is more sensitive than a 5-mm probe head, but the former requires a larger sample volume and accordingly more analyte. The 5-mm probe heads were the most common choice in inter-laboratory comparison/proficiency tests; in the selection of a probe head, its sensitivity for a particular nucleus is also important. For probe heads available, see catalogues of NMR spectrometer and probe head manufacturers.

Most common is a switchable probe head, which can be used to observe $^1$H and all NMR active nuclei from the low-frequency limit up to the frequency of $^{31}$P. The proton coil can be tuned for the observation of $^{19}$F. The switchable probe head is designed for either direct or inverse observation. The direct observation probe head is most sensitive for 1-D experiments on $^{13}$C and $^{31}$P. The inverse probe head in turn is most sensitive for the direct observation of $^1$H and indirect detection, for example of $^{31}$P, in 2-D experiments taking advantage of polarization-transfer phenomena.

A four-nucleus probe head with which $^1$H, $^{13}$C, $^{19}$F, and $^{31}$P can be observed is also useful. Such a probe head can be pretuned for each nucleus, and the switching between nuclei is easy and can even be automated. Sensitivity is comparable to that of the switchable probe head with direct observation.

Selective probe heads are used for optimal sensitivity for a particular nucleus. Sensitivity of a selective $^1$H-probe head is normally greater than that of a switchable probe head with indirect observation. With a selective X-nucleus (a nucleus other than proton) probe head, decoupling of protons is normally possible. Because of their limited usefulness, selective probe heads are rare in NMR laboratories. Other probe heads are also available, e.g. ones for triple resonance experiments and experiments utilizing pulsed-field gradients. In addition to their suitability for 2-D experiments, the gradients are particularly suitable for solvent suppression.

2.3 Automatic Operation

An automatic sample changer (ASC) is often an option for a spectrometer. The operator sets the samples into the rack of the ASC and predefines the experiments, which are then performed with automatic homogeneity adjustment, processing, and plotting of data. When the experiments for one NMR sample are completed, the sample is changed. In this way, the spectrometer can work unattended during nights and weekends. The ASC works best for recording spectra from standard NMR samples in which the concentration is relatively high. Requirements for optimal experimental performance for measuring test samples, which may contain anything from
organic liquids to aqueous liquids of high salt content, may be too demanding for the ASC.

The main requirements for measuring test samples are (a) separate tuning of the probe head for each sample and nucleus in order to guarantee optimum sensitivity, (b) accurate homogeneity adjustment even for the most difficult samples, in order to achieve the narrowest lines and pure line shape, and (c) plotting of expanded regions for spectra where the resonances of interest may be less than 1% of the intensity of the background resonances. Manual operation by an experienced operator is mandatory if highest quality spectra are to be guaranteed.

Automatic operation is possible without a sample changer if “macros” are available or programmable spectrometer software. After manual tuning for the observed nucleus, manual homogeneity adjustment, and a manual check for an acceptable line shape, defined experiments can be run one after the other with a single sample. A series of experiments can be run overnight or longer, with the computer taking care of the measurements. The data are plotted manually for evaluation and analysis.

The spectral analysis is carried out manually because automatic interpretation and library programs are normally not available. Difficulties in NMR and automatic interpretation are (a) high spectral background in spectra recorded from environmental samples, often leading to resonance overlap, (b) solvent dependence of chemical shifts (£), which affects the appearance of the spectrum, and (c) in the case of 1H NMR spectra, the complexity. The other spectra, particularly 13C[1H], are simple, but low sensitivity is then a problem.

2.4 Data Systems

The spectrometer computer is equipped with a computer operating system (e.g. a version of UNIX) and the specific operating system for the spectrometer. After the experiments, data can be stored on different media, sent through the internet, processed in various ways, and plotted.

3 EXPERIMENTAL

3.1 Solvents

Deuterated solvents are preferred for NMR samples. The solvents should be of spectroscopic grade or corresponding quality and should have a high enrichment of deuterium, preferably >99.5%. Deuterium oxide (D2O), chloroform-d1 (CDCl3), acetone-d6 (CD3CO), and dichloromethane-d2 (CD2Cl2) are common in the analysis of CWC-related chemicals, but many others [e.g. acetonitrile-d3 (CD3CN), methanol-d4 (CD3OD)] are available and may be suitable. The solvent is selected according to the requirements of the sample preparation. Where evaporation of the (protonated) solvent is not desirable, a small portion of the corresponding deuterated solvent is added to the sample [e.g. 5–10% (v/v)] for field/frequency stabilization.

The impurities in some solvents may disturb the analysis of low-ppm concentrations of CWC-related chemicals through resonance overlap. Traces of water are common in organic solvents, but the water can be removed by using a suitable drying agent in contact with the sample solution before transferring it to an NMR tube. A representative blank sample, if available, or a blind sample (solvents and reagents that have gone through the sample preparation path without having been in touch with the test sample) serves for excluding the resonances of the background and solvent chemicals from the spectrum of the test sample.

3.2 Chemical Shift References

Chemical shift references for calibration of the spectrum scale may be internal or external. An internal chemical shift reference substance is dissolved directly in the NMR sample solution that is measured. In the external method, a separate NMR sample is prepared, containing the reference substance(s) dissolved in the same solvent as used for the test sample. Alternatively, the reference substance may be placed in an insert (capillary) tube, as such (e.g. 85% H3PO4) or dissolved in the same solvent as used for the test sample. The insert tube is placed into the NMR sample to be analyzed, or into a separate NMR tube containing only the solvent. The spectrum is then recorded for the reference position.

To avoid overlap of the resonances of the reference substance and chemicals of interest, and a possible overdose of the reference substance, and also from the point of view of optimum magnet homogeneity, we recommend the external chemical shift reference method with use of a separate rather than an insert sample tube.

The external reference method is common in 31P NMR. The reference substance, 85% H3PO4 (phosphoric acid), is transferred in a cylindrical or spherical capillary tube to an NMR sample tube containing the same solvent as the test sample. Owing to its chemical reactivity, H3PO4 cannot be added as an internal reference substance. Although not an exact method,120 the resonance of H3PO4 is set at 0.00 ppm when the coaxial capillary tube system is used.

The most common reference chemicals in 1H and 13C NMR are tetramethylsilane (TMS; dissolves in organic solvents, δH = δC = 0.00 ppm), 3-(trimethylsilyl)-3,3,2,2-tetradeuteroisopropionic acid sodium salt (TSPA-d4;
dissolves in water/D₂O, δ_H = δ_C = 0.0 ppm), and 3-(trime-thylsilyl)propane sulfonic acid sodium salt (TSPSA; dissolves in water/D₂O, δ_H = 0.015 ppm, δ_C = 0.00 ppm). A common reference substance for \(^{19}\)F NMR is trichlorofluoromethane (CFCl₃; dissolves in organic solvents, δ_F = 0.00 ppm). The fluorine resonance of CFCl₃ consists of four lines with intensities (from high frequency down) 8:8:3:1; the second line from the high-frequency end is used as the scale origin.\(^{22}\)

Other reference substances are available and can also be used. Sometimes the resonance of the actual solvent can serve as a reference. Preferably, the referencing method used for the sample should be the same as that used for the authentic reference sample (or library spectrum), or at least the scale position should be corrected by a known factor. Whatever referencing method is used it needs to be reported in sufficient detail.

### 3.3 Nuclear Magnetic Resonance Sample Tube

NMR tubes are usually made of high-quality Pyrex glass. The tube is selected according to the size of the probe head, normally 5 or 10 mm (o.d.). Different qualities of tubes are available. Provided the sample solution is of good quality, thin-walled extra-high-quality NMR tubes give the best resolution, line shape, and sensitivity. Routine quality tubes for daily use (e.g. Wilmad 507-PP) are normally adequate, however. Usually the tube is sealed by a plastic cap, but other cap materials are also available. For the sake of safety in working with toxic chemicals, sealing of the tube by melting the top of it by flame may be advisable (an air-tight ampule is formed). Microcylinders and coaxial capillary inserts of different shapes, volumes, and materials are available for small sample amounts, external locking, external referencing, and corrosive materials (see catalogues of NMR tube sellers).

A simple method to remove dust, which even new NMR tubes may contain, employs a 10–20-mL plastic syringe, a 0.45-µm high-performance liquid chromatography (HPLC) filter unit suitable for water, a needle, distilled water, and an oven (at 45–55 °C). Rinse the NMR tube with 1-mL portions of filtered distilled water by shaking while the cap is on, until no dust is seen in the rinsing solution in the tube. Empty the NMR tube and put it open end down in a decanter glass, and into the oven for drying.

### 3.4 Sample Preparation

In principle, preparation of an NMR sample is simple: take a suitable amount (1–100 mg) of chemical to be analyzed, dissolve it in a selected solvent, add the chemical shift reference substance, and then transfer the sample with simultaneous filtration into an NMR tube. Attach a code label to the top of the NMR tube. General reading on sample preparation is available.\(^{23–25}\)

The quality of the results in NMR largely depends on the care with which the sample has been prepared. Not only should the NMR sample tube be of good (routine) quality, but also the sample solution in the tube should be free of nondissolved particles and dust.

NMR spectral parameters, i.e. chemical shift and coupling constant (J), may be considerably affected by the sample condition, i.e. solvent, pH, sample temperature, concentration, and choice of internal and/or external chemical shift references. Solvent and pH (in water/D₂O samples) have the greatest effect. The sample condition should therefore be the same as or comparable to that used for the authentic reference chemical (or library spectrum) and the blank sample.

A sample for NMR spectroscopy can be taken from several stages of the sample preparation path [see Sample Preparation for Analysis of Chemicals Related to the Chemical Weapons Convention and the literature\(^{14,18}\)]. Preferably, this would be a 5–10-mL portion of extract or of aqueous or organic liquid. Common to all these solutions is the large molar excess of \(^1\)H in the solvent compared with the amount of \(^1\)H in the possible target chemicals. This yields an intense solvent (e.g. H₂O, CH₂Cl₂) resonance in the \(^1\)H NMR spectrum, making the trace analysis difficult or even impossible. A usual procedure to avoid this problem is to replace the protonated solvent (e.g. H₂O) with the corresponding deuterated solvent (D₂O). Deuterated solvents are also used for the field-frequency lock of the spectrometer.

The solvent is replaced by evaporating the protonated solvent and adding the corresponding deuterated solvent in its place. The sample is concentrated during the evaporation; however, one must be alert to the danger of losing volatile chemicals at the same time. The sample solution is then transferred to an NMR tube and is ready for the experiments. Because NMR spectroscopy is a nondestructive technique, the sample can be used after the NMR experiments for other analyses.

Except for extraction, no separation methods have been used in the NMR sample preparations in interlaboratory comparison tests.\(^7–14\) Thus, the chemicals of interest, impurities, and background present in the original sample and in the extract were all present in the NMR sample. The advantage of this is that, generally, not much or nothing is lost, while the disadvantage is overlapping of the resonances of interest with resonances of other chemicals.

#### 3.4.1 Preparation of Nuclear Magnetic Resonance Samples from Aqueous or Organic Liquid or Extract

A portion of aqueous or organic liquid or extract reserved for NMR spectroscopy is filtered, if necessary,

\]
and concentrated by evaporation. The evaporation is carried out on a rotary evaporator (50°C, 35 mmHg for evaporation of water), or by a gentle flow of nitrogen gas (for organic liquid) with warming (40–50°C) or without. The small amount (ca. 1 mL) of solution left in the rotary evaporator is further evaporated nearly to dryness by a flow of nitrogen gas. To each concentrate, about 1 mL of the corresponding deuterated solvent (e.g. D₂O, CD₂Cl₂) is added and the solution is again evaporated nearly to dryness. These two steps are then repeated. The remaining solution is filtered through a cotton plug (or a plug of glass wool) placed in the neck of a Pasteur pipet into a washed, dust-free NMR tube.

Alternatively, an HPLC filter unit may be used for the filtration. The sample vessel is rinsed with a suitable amount of (deuterated) solvent and the rinsing solutions are added to the sample in the NMR tube. The pH of the aqueous liquid sample is determined, and can be adjusted with DCl and NaOD solution. For measurements carried out in a standard 5-mm (o.d.) NMR tube, about 0.6–0.8 mL of solvent is required, and for 10-mm tubes about 3–4 mL. If considered necessary, some of the extractions can be performed with deuterated solvents, which will simplify the sample-preparation procedure. Related practical sample preparations can be found in the literature.(10,12,14)

Because chemicals that distill easily or with water (e.g. pinacolyl alcohol) may be lost during rotary evaporation, an additional sample may be prepared for screening/analysis by taking a suitable amount of original aqueous liquid (e.g. 0.7 mL for a 5-mm o.d. tube), adding a small amount (e.g. 0.1 mL) of D₂O, determining the pH, and filtering the sample solution into an NMR tube. A similar non-evaporated NMR sample can be prepared from the organic extract.

If an internal chemical shift reference is to be used, a dilute solution of reference substance (e.g. TSPA-d₄) is prepared in the same solvent as used for the test sample (e.g. D₂O). A few microliters (or a suitable amount) of this reference solution are added to the evaporated sample solution before filtration into the NMR tube.

3.4.2 Preparation of Nuclear Magnetic Resonance Samples from Authentic Reference Chemicals

In a 2-mL vial, dissolve the selected amount of authentic reference chemical (e.g. 20 µL of mustard gas (HD)) in 0.8 mL of deuterated solvent (e.g. CDCl₃). [To ensure safety, always prepare NMR samples of toxic chemicals in a properly equipped fume cupboard or glovebox.] Using a Pasteur pipet, add an internal chemical shift reference three to four drops of TMS solution, prepared by dissolving three to four drops of TMS in 0.5 mL of solvent (CDCl₃ in this case). Tightly place a plug of purified cotton for a filter in the neck of a Pasteur pipet and fix the pipet on a clamp stand. Rinse the cotton plug with the sample solution, then let the solution flow into the washed, dust-free NMR tube. With a suitable vacuum and welding apparatus, flame seal the tube near its open end in a low vacuum.

Alternatively, instead of cotton, glass wool or a suitable HPLC filter unit may be used for the filtration. Before filtering the authentic reference sample solution (in D₂O) into the NMR tube, adjust the pH to the same value as in the test sample.

See Figures 2 and 3 for NMR conditions for samples of authentic sarin (GB) and tabun (GA) and Table 1 for conditions for some other authentic samples.

3.5 Experiments and Data Processing

3.5.1 Preliminary Preparation

The probe head is separately tuned and matched(23) for each sample and experiment. The magnetic field homogeneity is carefully adjusted(23) and, always before final accumulation, line shape and line width are checked by recording trial 1-D spectra with a few scans. Every experiment run in the laboratory should be logged in an experiment logbook; a useful reference entry would contain a run number, the date, the file name, the sample code, and the initials of the operator.

3.5.2 Experimental Conditions

Unlike the sample condition, the experimental parameters have only a minor effect on the NMR spectral parameters. Experimental parameters such as spectral width, flip angle, repetition time, number of points in the free induction decay (FID) and in the real spectrum, number of scans, and processing parameters need to be comparable to those used for the acquisition of the database spectrum or spectrum of the authentic reference chemical. The experimental parameters determine whether quantitative information can be obtained from an NMR spectrum; under certain experimental conditions the resonance area is directly proportional to the number of nuclei.(26)

1H and 31P NMR spectra are recorded with a normal one-pulse sequence or, alternatively, the 1H spectra are recorded with a sequence that allows simultaneous solvent suppression with presaturation(27) or a sequence that includes some other method of suppression; 13C(¹H) and 31P(¹H) spectra are recorded with proton broadband (composite pulse) decoupling,(28) and 31P spectra with gated proton decoupling.(29)

The experimental conditions are the following: spectral ranges (all approximate) are from −0.5 to 11 ppm in 1H NMR, from −40 to 120 ppm in 31P(¹H) and 31P NMR.
CHEMICAL WEAPONS CHEMICALS ANALYSIS

(certain types of phosphorus-containing chemicals, e.g. phosphonites and phosphites, may have larger chemical shifts and their observation needs an extended spectral window), from −80 to 5 ppm in $^{19}$F NMR, and from −5 to 230 ppm in $^{13}$C($^1$H) NMR, all relative to the respective references TMS, $\text{H}_3\text{PO}_4$, CFCI$_3$, and TMS (δ = 0 ppm). The number of points in the FID and in the real spectrum normally ranges from 32 K to 128 K. The number of scans is selected so as to obtain a sufficient signal-to-noise ratio (S/N). Pulses of 45–90° flip angles are used and the repetition time (pulse interval) is selected to be 3–6 s.

Note that because the relaxation times of the nuclei of the target chemicals are normally not known, these conditions are a compromise, and should be modified according to the case: shorter repetition time if the nuclei relax fast (this can be approximately checked from duration of the FID).

Experimental conditions for recording reference spectra from authentic chemicals are similar to those used for test samples. By way of example, Figure 2 shows the library NMR spectra of GB from the AC-Laboratory and Figure 3 those of GA from VERIFIN. The spectra are presented in their original form (size reduced from A4) to show layout and format of library spectra that have been acceptable to the Organisation for the Prohibition of Chemical Weapons (OPCW) Convention. The experimental conditions shown are the “standard conditions” used by the laboratory for the particular experiment.

3.5.3 Processing of Data

Usually, the FID is Fourier transformed after application of an exponential window function. The linebroadening factor is selected to provide a good S/N. As a rule, the line broadening is selected according to the width of a narrow singlet resonance $-\text{in }^1\text{H NMR}$. The resolution of the spectrum may be enhanced, though with reduced sensitivity, if the FID is multiplied, for example by a suitable Gaussian shape function, before Fourier transformation. Resolution enhancement is applied to better resolve the details of resonances, as in the case of resonance overlapping. Zero filling, i.e. adding zero data points at the end of the FID prior to Fourier transformation, is sometimes necessary for proper representation of the line shape, particularly when resolution enhancement is performed. Baseline correction may be needed in cases where very-small-intensity resonances need to be presented as large expansions.

3.5.4 Plotting of Data

A spectrum is plotted in its full width and as expanded regions. The spectrum is plotted on paper, always with a title that assigns a link between the actual spectrum, the sample (sample code), and the entry in the experiment logbook (e.g. a source reference code). The expanded regions of the spectrum of the sample, the blank (if available), and the authentic reference chemical should be presented at the same scale and be sufficiently detailed. The experimental conditions are also printed out. Spectrum integration and peak picking are done where necessary.

4 QUALITY CONTROL

4.1 Quality Management System

Work performed in a laboratory must be traceable. This is achieved when all relevant information from sample preparation to experiments and reporting of data are recorded on paper or stored in a computer. In practice, this requires a quality management system of the laboratory. Continued effort toward quality in the laboratory and, if possible, national accreditation of the laboratory is recommended.

4.2 Data Quality

The quality of an NMR experiment can be assessed from the sample spectrum. In an optimal spectrum a singlet resonance line is both narrow and symmetric, the S/N is high, and all resonances of interest are seen. The spectrum quality is a measure known to the laboratory after work with the particular spectrometer/magnet and probe head on different samples; thus no limits can be suggested for the width of a singlet resonance. An experienced operator notices rather easily whether the problems with line shapes arise from a poor sample or inadequate homogeneity adjustment.

Resonance overlap is a real problem in NMR when the technique is applied for chemical identification: details of all resonances of the identified chemical should be revealed (see section 6.2). In particular, one should consider whether the outer lines of multiplets are being seen, e.g. those of the doublet of septets of the methine proton of GB (cf. Figure 2a); if the problem is poor S/N, more scans should be acquired in the experiment. Further homogeneity adjustment for a narrower line width and/or resolution enhancement may partially solve the problem of resonance overlap.

4.3 Spectrometer Performance

In accordance with the quality control (QC) regime of the laboratory, the performance of the spectrometer should be checked and documented regularly. The specifications
set by the spectrometer manufacturer are considered as the principal target to be obtained. Each experiment for the check of spectrometer performance is logged in the experiment logbook. The spectrometer-performance tests comprise checking of the 1H line shape and sensitivity for a probe head and for a selected X-nucleus (a 1H resolution test may be unnecessary if the 1H line-shape test passes well). Other tests include checking of the radio-frequency field strengths of the observation and decoupling channels. A recommended practice for S/N determination in Fourier transform NMR is described in Standard Definitions of Terms, Symbols, Conventions, and References Relating to High-resolution NMR Spectroscopy (ASTM Standards, E 386-90). Spectrometer manufacturers provide instructions for S/N determination and the other tests [see also Braun et al.122].

4.4 Tests and Test Samples

Testing of the spectrometer performance requires a variety of test samples, usually provided by the spectrometer manufacturer. A set of tests and test samples may be as follows:

- 1H line shape, resolution, and spinning side band test;
- 1H sensitivity: 0.1% ethylbenzene in CDCl3;
- 31P sensitivity: 0.0485 M triphenyl phosphate in CDCl3;
- 19F sensitivity: 0.05% trifluorotoluene in CDCl3;
- 13C sensitivity: 10% ethylbenzene in CDCl3;
- 1H resolution test: 5% of o-dichlorobenzene in acetone-d6;
- temperature calibration: 80% of ethylene glycol in DMSO-d6 and 4% of methanol in methanol-d4.

Specifications for a probe head/field strength (magnet) combination are given by the spectrometer manufacturer for line shape, sensitivity, resolution, and radio-frequency field strengths. A specific test is considered “passed” when the specification value is met.

5 APPLICATIONS

5.1 Main One-dimensional Experiments

The most important experiments (see section 3.5) in the verification of CWC-related chemicals by NMR spectroscopy are 1H, 31P[1H], 19F, 31P, and 13C[1H] (listed in the order of importance in interlaboratory comparison/proficiency tests; Figure 1). These 1-D experiments are useful both for the identification of chemicals and in structure elucidation. The 1H, 13C[1H], 19F, 31P[1H], and/or 31P NMR spectra can be recorded one after the other from the same NMR sample. The 1H NMR experiment is most sensitive and often will be run first. Specific couplings in the 1H spectrum may indicate the presence of phosphorus or fluorine, which is then confirmed by 31P[1H] and/or 31P and 19F experiments. 13C[1H] experiments are performed if necessary and if the sample concentration is high enough. The literature can be consulted for general reading on NMR,31 31P and multinuclear NMR,30,31 and practical performance of experiments.22

5.1.1 Screening

The presence of phosphorus- or fluorine-containing chemicals above the detection limit can be checked by running 31P[1H] and 19F NMR experiments. Normally, in environmental samples, no organic phosphorus- or fluorine-containing chemicals exist in the background, which makes these experiments useful as a screening method. Fluorine observation has an advantage because the sensitivity is nearly as high as for protons. Although 1H NMR also offers a sensitive screening method, there could be interference from a high proton background. The presence of phosphorus-containing chemicals could then not be ruled out simply by recording the 1H spectrum.

5.1.2 1H Nuclear Magnetic Resonance

The 1H NMR spectrum (Figures 2a and 3a) provides information on the number and type of protons [number of resonances, areas of resonances, δH (ppm)] in the molecule and, in the form of coupleings [J (Hz)], may reveal other magnetic atoms (e.g. 1H, 31P, 19F) one to four bonds away from a hydrogen atom. (The maximum distance of four bonds between the coupling nuclei should be considered approximate.) Note that the experimental conditions required for quantitative work, as given in section 3.5.2, may not necessarily have been obtained, and the areas of the resonances should therefore be considered only approximate. In general, much longer repetition times are needed for quantitative conditions.

5.1.3 31P[1H] and 31P Nuclear Magnetic Resonance

The 31P[1H] NMR spectrum (Figures 2b and 3b) provides information on the number and type of phosphorus atoms (number of resonances, areas of resonances, δP) in the molecule and, in the form of couplings, may reveal other magnetic atoms (e.g. 31P, 19F) one to four bonds from a phosphorus atom. (The maximum distance of four bonds between the coupling nuclei should be considered approximate.) The notation 31P[1H] means that, when 31P is observed, protons are irradiated so that the J-coupling
between protons and phosphorus disappears; however, the interaction with other magnetic nuclei remains.

The $^{31}\text{P}$ NMR spectrum (Figures 2c and 3c) provides information on the number and type of phosphorus atoms (number of resonances, areas of resonances, $\delta_P$) in the molecule and, in the form of couplings, may reveal other magnetic atoms (e.g. $^1\text{H}$, $^{31}\text{P}$, $^{19}\text{F}$) one to four bonds from a phosphorus atom. (The maximum distance of four bonds between the coupling nuclei should be considered approximate.) Note that the $^{31}\text{P}[^1\text{H}]$ and $^{31}\text{P}$ NMR spectra are not quantitative and the areas of the resonances should be considered only approximate. In addition, a quantitative $^{31}\text{P}[^1\text{H}]$ experiment utilizes an inverse gated pulse sequence.\(^{(32)}\)

5.1.4 $^{19}\text{F}$ Nuclear Magnetic Resonance

The $^{19}\text{F}$ NMR spectrum (Figure 2d) provides information on the number and type of fluorine atoms (number of resonances, areas of resonances, $\delta_F$) in the molecule and, in the form of couplings, may reveal other magnetic atoms (e.g. $^1\text{H}$, $^{31}\text{P}$, $^{19}\text{F}$) one to four bonds from a fluorine atom. (The maximum distance of four bonds between the coupling nuclei should be considered approximate.) Note that the experimental conditions required for quantitative work, as given in section 3.5.2, may not necessarily have been obtained, and the areas of the resonances should therefore be considered only approximate. In general, much longer repetition times are needed for quantitative conditions.

5.1.5 $^{13}\text{C}[^1\text{H}]$ Nuclear Magnetic Resonance

The $^{13}\text{C}[^1\text{H}]$-NMR spectrum (Figures 2e and 3d) provides information on the number and type of carbons (number of resonances, areas of resonances, $\delta_C$) in the molecule and, in the form of couplings, may reveal other magnetic atoms (e.g. $^{31}\text{P}$, $^{19}\text{F}$) one to four bonds from a carbon atom. (The maximum distance of four bonds between the coupling nuclei should be considered approximate.) Note that the $^{13}\text{C}[^1\text{H}]$ NMR spectra are not quantitative and the areas of the resonances should be considered only approximate. In addition, a quantitative $^{13}\text{C}[^1\text{H}]$ experiment utilizes an inverse gated pulse sequence.\(^{(35)}\)

5.2 $^1\text{H}[^{31}\text{P}]$, $^1\text{H}[^{19}\text{F}]$, and $^1\text{H}[^{1}\text{H}]$ Nuclear Magnetic Resonance Experiments

In $^1\text{H}[^{31}\text{P}]$, $^1\text{H}[^{19}\text{F}]$, and $^1\text{H}[^{1}\text{H}]$ NMR experiments a proton is observed, while phosphorus, fluorine, or proton is decoupled. The phosphorus and fluorine are decoupled either selectively or with broad-band irradiation, while the proton is irradiated selectively. In each case a $^1\text{H}$ NMR spectrum simplified by the removal of the effect of the irradiated nucleus to the spectrum is obtained, i.e. all nuclei that are coupled to the decoupled nucleus/nuclei exhibit a simplified resonance pattern. Comparison of the normal $^1\text{H}$ NMR spectrum with the decoupled spectrum may help in interpretation of the former and in resolution of the molecular structure. Suitable 2-D experiments (homo- and heteronuclear correlation) provide comparable information; however, the 1-D experiments are quicker to perform and show the resonances in a more detailed manner.

5.3 Relevant Two-dimensional Techniques

2-D chemical shift correlation NMR techniques may be useful in supporting the verification analysis (Figure 1). In particular, they may be useful in the structure elucidation of an unknown CWC-related chemical. In 2-D spectra, the information is spread in the form of correlations over an $xy$-plane instead of being contained in a single spectrum curve as in 1-D spectra. Correlations connect resonances of the same or different types of nuclei of a molecule and give information on how close the nuclei yielding the resonances are. Most of the techniques make use of a $J$-coupling constant (a spin–spin coupling through chemical bonds). The rule that the size of the coupling constant (and the intensity of correlation) decreases as the distance between the coupled nuclei increases is roughly valid. Because of the two dimensions and the correlations, spectral analysis may be possible even in the presence of strong background. The analysis of mixtures is more straightforward with 2-D techniques because the correlations do not overlap as readily as do the resonances in a 1-D spectrum.

By way of example, useful 2-D techniques are correlation spectroscopy (COSY), total correlation spectroscopy (TOCSY), heteronuclear multiple quantum coherence (HMQC), and heteronuclear multiple quantum coherence/total correlation spectroscopy (HMQC/TOCSY).\(^{1,2,22}\) An excellent technique is a proton detected proton–phosphorus correlation experiment with combined HSQC and TOCSY that has been used for the analysis of CWC-related chemicals during an international interlaboratory proficiency test.\(^{13}\) In this technique, protons of an alkyl phosphonofluoridate, for example, show correlations to the phosphorus nucleus of the molecule, which is then used to assign from the 1-D $^1\text{H}$ spectrum the resonances that belong to this particular chemical. A 2-D NMR spectrum might also serve as a library or reference spectrum in the identification of a chemical.

5.4 Scheduled Chemicals

The suitability of NMR spectroscopy and the detection limits for the analysis of the Schedule 1–3 chemicals\(^{(15)}\)
are summarized below. Riot control agents and vomiting agents are normally soluble in organic solvents, and are readily analyzed by NMR.\textsuperscript{(11,33)}

5.4.1 Schedule 1 Chemicals

Almost all Schedule 1 chemicals are soluble in the organic NMR solvents used in verification (see section 3.1) and can be analyzed by NMR spectroscopy. Saxitoxin (1.A.7) and ricin (1.A.8) differ from the others. Both are derived from natural sources—the former is a paralytic shellfish poison and the latter a glycoprotein toxin.\textsuperscript{(34)} Analytical methods [Recommended Operating Procedures (ROPs)] have not been established for either chemical. NMR data of saxitoxin in D\textsubscript{2}O have been reported.\textsuperscript{(35,36)} By way of example, Table 1 presents the NMR spectral parameters of GB, GD, GA, VX, HD, Q, T, L, HN-1, methyl phosphonyl difluoride, and chlorosarin.

5.4.2 Schedule 2 Chemicals

All Schedule 2 chemicals are analyzable by NMR, except arsenic trichloride, which does not possess a useful nucleus. Either an organic solvent or D\textsubscript{2}O is used. Note that the hydrolysis products of alkylphosphonofluoridates (1.A.1), alkylphosphonothiolates (1.A.3), alkylphosphonyl difluorides (1.B.9), alkylphosphonites (1.B.10), chlorosarin (1.B.11), and chlorosoman (1.B.12), which have an alkyl group (Me, Et, n-Pr, or i-Pr) linked directly to a phosphorus, all belong to Schedule 2, group B.4, and NMR analysis for them is made either in D\textsubscript{2}O or in an organic solvent. By way of example, NMR spectral parameters of isopropyl methylphosphonate, pinacolyl methylphosphonate, methylphosphonic acid, O-ethyl methylthiophosphonate, N,N-dimethylphosphoramidic dichloride, benzilic acid, N,N-diisopropylaminoethan-2-ol, and thiodiglycol are presented in Table 1.

5.4.3 Schedule 3 Chemicals

Most of the Schedule 3 chemicals are readily analyzed by NMR: trimethyl phosphate, triethyl phosphate, dimethyl phosphate, diethyl phosphate, ethyldiethanolamine, methyltriethanolamine, and triethanolamine. Organic solvents or D\textsubscript{2}O are used. Although chloropicrine and the gases phosgene (3.A.1), cyanogen chloride (3.A.2), and hydrogen cyanide (3.A.3) can also be analyzed by NMR, their identification by other methods is more reliable. Phosphorus oxychloride (3.B.5), phosphorus trichloride (3.B.6), and phosphorus pentachloride (3.B.7) react readily with moisture, but in principle can be analyzed by NMR in a dry organic solvent. Sulfur monochloride (3.B.12), sulfur dichloride (3.B.13), and thionyl chloride (3.B.14) do not possess an NMR nucleus suitable for verifying them. By way of example, NMR spectral parameters of diethyl phosphate and ethyldiethanolamine are presented in Table 1.

5.5 Detection Limits

The detection limit of a chemical in NMR depends on its NMR properties (e.g., number of equivalent nuclei, presence and extent of couplings), the magnetic field strength of the spectrometer, the number of pulses, the flip angle used, the observed nucleus and its relaxation, the NMR tube diameter, the sample matrix, and the magnet shimming. Detection limits in \textsuperscript{1}H, \textsuperscript{13}C, \textsuperscript{19}F, and \textsuperscript{31}P observation should all be determined, remembering, however, that the detection limit for a reference chemical does not guarantee the same detection limit for the chemical in a real sample. Typically the detection limit of a chemical when \textsuperscript{1}H is observed at 400 MHz or \textsuperscript{19}F at 376 MHz may be 1 µg mL\textsuperscript{-1} (1 ppm). Almost one order of magnitude more of the analyte is required for phosphorus observation (5 ppm at 162 MHz), and recording of \textsuperscript{13}C\textsuperscript{(1}H\textsuperscript{)} spectra may be futile in concentrations below 100 µg mL\textsuperscript{-1} (100 ppm).

6 ANALYSIS

6.1 Acquired Nuclear Magnetic Resonance Data

The spectral data required to support an identification by NMR are the sample spectrum, the reference spectrum, and the spectrum of a blank sample (if available). All should be recorded under comparable conditions. The reference spectrum may be from a library or database, or it may be a spectrum of a closely related chemical; in this last case spectral interpretation must be enclosed.\textsuperscript{(37)} Other 1-D and 2-D NMR spectra (see sections 5.2 and 5.3) may have been recorded from the test sample to support the interpretation, and identification.

6.2 Identification Criteria

As the main rule in verification, unambiguous identification of a CWC-related chemical should be based on at least two analytical, preferably different spectrometric, techniques (e.g., gas chromatography/mass spectrometry (GC/MS) and NMR) giving consistent results.\textsuperscript{(37)} The NMR spectral parameters for a chemical should agree with the corresponding values in the database or spectrum library, or with the parameters derived from the spectrum of an authentic reference chemical. According to the identification criteria,\textsuperscript{(18)} the values of \(\delta\)\textsubscript{1H}, \(\delta\)\textsubscript{C}, and \(\delta\)\textsubscript{F} should agree with the corresponding values in the database or library or the values of an authentic reference chemical.
within limits ±0.1 ppm, and those of δ_P within ±1 ppm. The values of coupling constants J_{1H,1H}, J_{1H,1F}, J_{1H,31P}, J_{31P,1H}, J_{1P,1H}, and J_{1F,1H} should agree within limits of ±0.5 Hz. In addition, the resonance patterns and their intensities must match. Normally, when the conditions of the test sample and the reference sample are comparable, the differences in the NMR parameters are much less than suggested above; sometimes, within reasonable limits and when credibly explained, greater differences may be acceptable.

Sample conditions (solvent, pH in water, chemical shift references, concentration) and experimental conditions should correspond in the sample and reference sample. Sample concentration and the experimental conditions are less critical for the NMR spectral parameters.

Other chemicals (matrix) present in the sample, especially at low analyte concentration, may affect the NMR spectral parameters and how the resonances are revealed. A general requirement for a spectrum acceptable for identification is that resonances of other chemicals do not overlap with resonances of the identified chemical. Partial overlapping may be acceptable if the resonance of the identified chemical can still be credibly explained. Where insufficient data are obtained, for example owing to severe overlapping, the resonances revealed may still be useful in supporting identifications based on other analytical techniques.

### 6.3 Interpretation

The sample spectra are compared with the corresponding spectra recorded from the blank sample (if available), and the differences are investigated. If the blank sample represents the background well, the resonances that are not from the background can be determined directly. Obtaining a representative blank sample from a contaminated environmental site will not always be a realistic possibility, however. Initial interpretation of the spectra may reveal a need for further sample preparation and experiments (Figure 1).

Indicative structural details may be revealed. For example, methyl, ethyl, propyl, and isopropyl groups directly linked to phosphorus will show different resonance patterns in 1H NMR spectra. The 31P{1H} NMR spectrum can reveal the presence of phosphorus-containing chemicals and, in the case of a large coupling constant (due to a P–F bond, see Figure 2b), the presence of fluorine. The number of resonances and their integrated areas may give an idea of the number of chemicals present.

Note that nerve agent homologs that possess the same atoms one to three bonds apart from phosphorus may show similar phosphorus or fluorine resonances at comparable chemical shifts. Thus an analysis based solely on 31P and/or 19F NMR spectra may lead to an erroneous identification. Identification should not be based solely on 31P{1H} NMR spectra either. In any identification by NMR spectroscopy, 1H NMR is recommended as the first method of choice.

In the case of an unknown chemical, or where resonance overlap occurs, it may be necessary to call upon the full arsenal of NMR methods. To confirm a heteronuclear coupling the normal 1H NMR spectrum is compared with 1H{19F} and/or 1H{31P} NMR spectra. After this, and in particular where a strong background is present, the various 2-D NMR spectra are recorded. Homonuclear chemical shift correlation experiments such as COSY and TOCSY (or some of their variants) provide information on coupled protons, even networks of protons,(1) while the inverse detected heteronuclear correlation experiments such as HMQC and HMQC/TOCSY provide similar information but only for protons coupling to heteronuclei, e.g. the pairs 1H–31P and 1H–13C. Although interpretation of these data provides abundant information on the molecular structure, the results obtained with other analytical or spectroscopic techniques must also be taken into account. The various methods of MS and gas chromatography/Fourier transform infrared (GC/FTIR) spectroscopy supply complementary information to fully resolve or confirm the structure. Unambiguous identification of an unknown chemical requires consistent results from all spectrometric techniques employed.

### 6.4 Data Evaluation

In the evaluation of acquired NMR data one must consider whether the quality of the spectra and other accompanying information are sufficient for identification, or whether the data should only be regarded as support to an identification made by other techniques. One must consider whether all resonances of the chemical were revealed (S/N; occurrence and significance of overlapping resonances of other chemicals), whether the resonance patterns in the sample and reference spectra match and whether they are correctly interpreted, whether the sample conditions were comparable to those of the reference sample, whether the reference data are of adequate quality, and, in the case of interpretation, how the related data supported the identification.(37)

### 6.5 Identification

Identification by NMR of a CWC-related chemical is made through reference to spectra {1H, 13C{1H}, 19F, 31P{1H}, and/or 31P} included in a spectral library, through comparison with a spectrum of the authentic reference chemical, or through spiking the test sample with an authentic reference chemical. The spectrum of a
Figure 4. Expanded regions of $^1$H NMR spectra recorded from (a) a soil sample (pH 8.2) and (b) a blank soil sample in the Fourth Official OPCW Proficiency Test (May 1998). The soils were extracted with water, the extract was concentrated, and the remaining water was replaced with D$_2$O. (c) Spectrum of authentic thiodiglycol (pH 6.3), which was identified in the soil sample. The $^1$H chemical shifts were 2.763 and 3.758 ppm in (a) and 2.757 and 3.755 in (c); the coupling constant was 6.3 Hz in both spectra. The experimental conditions in all spectra were similar.

blank sample (if available) is examined for comparison. Identification of a chemical is obtained if all the identification criteria are met. Identification made by spiking the sample with the suspected chemical requires exact overlapping of the resonances. By way of example, the $^1$H NMR spectra for the identification of thiodiglycol in a soil sample in the Fourth Official OPCW Proficiency Test are presented in Figure 4.

6.6 Nuclear Magnetic Resonance Spectra of Sarin and Tabun

The $^1$H, $^{31}$P($^1$H), $^{31}$P, $^{13}$C($^1$H), and $^{19}$F NMR spectra of GB and GA are shown in Figures 2 and 3. The spectra of GB (Figure 2a–e) are from the Atlas of NMR Spectra of the AC-Laboratory and the spectra of GA (Figure 3a–d) from VERIFIN’s NMR Spectrum Library. Interpretations of the spectra are given below. The chemical shifts of the nuclei are not discussed since they can be explained with use of the common chemical shift correlation rules found in textbooks.($^{3,4,30}$)

In the $^1$H NMR spectrum of GB (Figure 2a), protons H-a yield a doublet of doublets due to couplings to phosphorus and fluorine. This is typical of all O-alkyl methylphosphonofluoridates. Proton H-b shows a doublet of septets due to coupling to phosphorus and the six methyl protons. Protons H-c and H-c' are diastereotropic and resonate as separate doublets; the intensity of the former is lower because of the different long-range couplings to phosphorus and fluorine. The $^{31}$P($^1$H) spectrum (Figure 2b) shows a typical doublet due to a large $^3$J$_{P,F}$. The $^{31}$P spectrum (Figure 2c) shows in addition doublets of quartets through couplings of phosphorus to H-b and H-a, respectively. In general, this kind of resonance is interpreted as indicating the structure CH–O=P(=O)(CH$_3$)$_2$F, and does not necessarily identify GB. The $^{19}$F spectrum (Figure 2d) reveals a doublet of quartets due to couplings with the phosphorus and protons H-a, thus giving an indication of substructure O=P(=O)(CH$_3$)$_2$F. Carbons C-a and C-c (Figure 2e) yield a doublet of doublets due to couplings to phosphorus and fluorine, and C-b and C-c' doublets due to coupling to phosphorus.

In the $^1$H NMR spectrum of GA (Figure 3a), protons H-a yield a typical doublet due to coupling with phosphorus. Protons H-b show a resonance that resembles a doublet of quartets; however, the protons are diastereotropic with a small chemical shift difference and reveal a higher-order resonance. The couplings and chemical shifts can be analyzed with use of a spectral analysis program. Protons H-c yield a doublet of triplets with a four-bond coupling to phosphorus and couplings to H-b and H-b0. The $^{31}$P resonance (Figure 3b) shows a singlet at a chemical shift typical for alkyl N,N-dialkylphosphoramidocyanidates. The $^{31}$P resonance (Figure 3c) resembles a nonet; however, the correct interpretation is a doublet (8.6 Hz) of doublets (9.8 Hz) of septets (11.3 Hz), but because of the broad lines the resonance is not seen in detail. All resonances in the $^{13}$C($^1$H) spectrum (Figure 3d) of GA are doublets due to phosphorus couplings.

6.7 Nuclear Magnetic Resonance Spectral Parameters of Selected Chemical Weapons Convention-related Chemicals

NMR spectroscopic parameters, sample conditions for selected scheduled CW agents and some of their precursors and hydrolysis products are presented in Table 1. The NMR spectral parameters are given in CDCl$_3$ or D$_2$O, or both (sometimes at different pH values). Resonances of the chemicals can be assigned from the data, but the assignments are not alone sufficient for identifications.

7 DATABASES

In the following, we list the requirements for the construction of an in-house NMR spectrum library for verification of CWC-related chemicals and briefly describe the OPCW Analytical Database and the VERIFY database (VERIFIN’s analytical reference database).
7.1 Requirements for an In-house Library

The main requirements for the construction of an in-house NMR spectral library for verification of CWC-related chemicals may be listed as follows:

- All \(^1\text{H}, \text{ }^{13}\text{C}(^1\text{H}), \text{ }^{19}\text{F}, \text{ }^{31}\text{P}(^1\text{H}), \text{ and } ^{31}\text{P} \text{ NMR spectra relevant to the molecular structure should be included (cf. Figures 2 and 3).}
- Spectra should be recorded with the authentic chemical dissolved in a commonly used NMR solvent, e.g. CDCl\(_3\) or D\(_2\)O. Since the solvent, and the pH in aqueous samples, may affect the appearance of the spectrum, particularly in \(^1\text{H} \text{ NMR, it is advisable to record spectra in different solvents (e.g. CDCl}_2, \text{ acetone-}d_6 \text{) and at different pH values (e.g. pH 0; pH ca. 7 or non-adjusted; pH 14).}
- NMR spectral parameters that can be easily extracted from the spectrum should be included, and the spectrum quality should be evaluated. The authentic chemical must be relatively pure so that there is no disturbing overlap of the resonances of the authentic chemical. In evaluation of the spectra, the laboratory should follow the OPCW evaluation criteria (see section 7.2).
- MS and/or IR spectroscopic analyses of the same authentic chemical should have been done to confirm the identity.

The principal contents of an NMR spectrum library page are as follows (see Figures 2 and 3).

- spectrum type;
- full-width spectrum and sufficient expansions to reveal the spectral details;
- chemical information (name, CAS number, structure);
- NMR spectral parameters (chemical shifts and coupling constants);
- sample conditions, experimental conditions, and data processing conditions;
- spectrum quality (line width) and traceability (source reference).

7.2 The Organization for the Prohibition of Chemical Weapons Analytical Database

An important part of implementing the CWC is establishing reliable verification mechanisms. As the analysis of samples taken on the occasion of inspections is one part of this mechanism, the availability of collections of analytical data is essential. The OPCW, as the body responsible for the implementation of the CWC, wishes to have its own Analytical Database, which contains as much data on CWC-related chemicals as possible. Since on-site analysis by IR and in particular MS is planned for future verification activities, libraries of IR and mass spectra are mandatory. Although NMR spectroscopy is not suitable for on-site analysis, it is nevertheless considered an essential technique for laboratories specialized in the detection and identification of CW agents and related chemicals. Qualified laboratories from all parts of the world were therefore asked to submit their IR, mass, and NMR spectra to be included in the OPCW Analytical Database.

An atlas of NMR spectra of the OPCW Analytical Database has been compiled with the assistance of dedicated laboratories worldwide. The efforts of the laboratories and the OPCW have yielded a useful high-quality NMR spectral database. The only factor limiting its usefulness could be the difference of the instruments (in magnetic field strength and resonance frequency) that were used, because the resonance frequency may affect the spectrum appearance, in particular in \(^1\text{H} \text{ NMR. However, this is not considered to be a serious problem because many of the spectra were recorded on 300–400 MHz instruments whose spectra do not differ much from those recorded at 200 or 500 MHz. The difference between the two extremes may be larger. The OPCW requires that all spectra to be included in the OPCW Analytical Database be evaluated.}

On behalf of the OPCW, the submitted spectra were evaluated by groups of specialists. It was decided that only 1-D \(^1\text{H}, \text{ }^{13}\text{C}(^1\text{H}), \text{ }^{19}\text{F}, \text{ }^{31}\text{P}, \text{ and } ^{31}\text{P}(^1\text{H}) \text{ NMR spectra recorded on FT spectrometers with a proton frequency of 200 MHz or higher should be included in the database.}

The spectra were evaluated according to the following main criteria:

- the spectrum must be consistent with the assigned structure;
- the name, CAS number (where available), and chemical structure with numbering of atoms must be indicated on the spectra;
- resonances must be assigned where reasonably possible;
- coupling constants must be included where easily extractable;
- expansions must be displayed where relevant;
- resonances of impurities must be marked with asterisks;
- resonances of impurities must not overlap the resonances of the chemical of interest;
- the solvent and pH (if relevant) must be specified;
- the reference chemical must be indicated;
- if the reference chemicals are other than TMS or TSPA-\(d_4\) for \(^1\text{H}, \text{ TMS for } ^{13}\text{C}(^1\text{H}), \text{ external } \text{H}_3\text{PO}_4 \text{ for } ^{31}\text{P}, \text{ and CFCl}_3 \text{ for } ^{19}\text{F} \text{ set at 0 ppm, their chemical shifts must be specified;}

• the spectrum must have been recorded with adequate resolution to enable all required information to be derived;
• the spectra must be phased correctly;
• the S/N must be adequate for the detection of all relevant signals;
• the type and frequency of the spectrometer must be indicated;
• the spectral width must be indicated.

Even before the CWC entered into force, the group of specialists approved some 900 NMR spectra recorded from 205 chemicals. It was decided to compile the accepted spectra as paper copies. A first version of the resulting atlas of NMR spectra was certified in February 1998. The process of extending the OPCW Database, which is to be made available on request to member states, is in continuous progress.

7.3 VERIFY Database
VERIFY is a computerized database designed for the storage, management, and search of chemical and analytical reference data. Properties and contents of the NMR part of VERIFY are as follows:

• NMR spectrum;
• chemical information;
• spectrum identification code and spectrum type;
• molecular structure and numbering of nuclei;
• NMR spectral parameters (chemical shift and coupling constant data) for nuclei;
• sample and experimental conditions;
• instrument information;
• capability for display, expansion, and printing of spectra; importing and exporting of spectra in JCAMP-DX format; no capability for spectral search.

The first versions of VERIFY were designed to work in the VAX environment, but the new version will work on a personal computer (PC) platform. The advantages of the computerized version relative to the paper version of the NMR library are easier access to the spectra and data search routines.

8 PERSPECTIVES AND FUTURE DEVELOPMENTs
8.1 Liquid Chromatography/Nuclear Magnetic Resonance
LC and supercritical fluid chromatography (SFC) have been combined on-line for the separation of analytes prior to their detection by NMR [the literature can be consulted for LC/NMR and SFC/NMR]. Although none of these techniques has yet been used in the analysis of CWC-related chemicals, their application in the field of verification is likely to begin soon.

8.2 Ultrahigh-field Spectrometers
A 400 MHz spectrometer is today a mid-frequency instrument. With a higher-field spectrometer, the detection limit is lower and the resonances are better dispersed, thus solving in part the problem of resonance overlap. By way of example, a $^3$H sensitivity of $1234 : 1$ (0.1% ethylbenzene; cf. section 4.4) was obtained on an 800 MHz spectrometer. This means that roughly one order of magnitude less chemical can be detected.

8.3 “Nano” Probe Technology
Less than 1-$\mu$g quantities of analytes in about 50–60 $\mu$L of solvent can be detected with a novel probe head known as the “nano” probe. Although with this probe head the absolute amount of a chemical needed for a useful spectrum is low, the problem of resonance overlap remains.

9 COMPARISON WITH OTHER SPECTROMETRIC TECHNIQUES
The main advantages of NMR spectroscopy in verification of CWC-related chemicals are as follows:

• At sufficient concentration and in the absence of disturbing background resonances, NMR is the superior method both for the identification of known chemicals and for the structural elucidation of unknown chemicals. Its usefulness in identification is attributable to the fingerprint nature of spectra, while the usefulness in structural elucidation rests on the structural specificity of the spectra. The wide variety of routine 1-D and 2-D experiments available is of assistance in both identifying of chemicals and structure elucidation.
• Most of the scheduled chemicals are directly analyzable by NMR. The spectra can be recorded in aqueous or in organic liquids from acidic, neutral, or basic chemicals, and from alkylated and protonated salts.
• Because NMR is a nondestructive method, the NMR samples can be used for the preparation of samples for other analytical techniques. (Note that in some cases the deuterated solvent may deuterate the chemicals of interest affecting their detection, for example by GC/MS.)
The main disadvantages of NMR are that

- there may be background resonances and, therefore, possible overlap of resonances of the chemicals of interest;
- there is no separation method for NMR comparable to GC for MS and FTIR (see section 8.1, however);
- sensitivity is low: the detection limits are high compared with MS and FTIR;
- NMR is not suitable for on-site analysis.

ACKNOWLEDGMENTS

Most of the authentic chemicals used for NMR analysis in this work were provided by the AC-Laboratory, Spiez, Switzerland. We wish to thank the AC-Laboratory for this gift and we also warmly thank Dr Walter Aue of the same laboratory for his comments on the manuscript.

15. ‘Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on their Destruction’. Signed in January 1993. Printed and distributed by the OPCW/PTS. The Depository of this Convention is the Secretary-General of the United Nations, from whom a certified true copy can be obtained.
Preparations of analytical samples from air, aqueous liquid (water), soil, active charcoal, wipe, concrete, paint, rubber, and other polymeric samples for off-site analysis are presented in section 2, and preparations of analytical samples from aqueous liquid (water), soil, and wipe samples for on-site analysis, are covered in section 3. Preparations for on-site analysis are as described in the standard operating procedures (SOPs) of the international organization responsible for verifying the Convention (Technical Secretariat of the Organization for the Prohibition of Chemical Weapons) and those for off-site analysis are as described in the corresponding recommended operating procedures (ROPs). Section 4 examines the question of quality control (QC) in sample preparation and section 5 the important matter of safety in handling samples containing CWC-related chemicals. Section 6 reports on the use of the methods in international comparison and proficiency tests.

1 INTRODUCTION

The reliable verification of chemicals related to the CWC depends essentially on the collection of good samples and well-planned, effective, and reasonably simple sample preparations suitable for the method of analysis. The collection of good samples is arguably the most critical part of a successful analysis and this is discussed in a separate article (see Sampling, Detection and Screening of Chemicals Related to the Chemical Weapons Convention). For its part, proper preparation of samples requires a thorough understanding of the behavior of the various types of chemical in different sample matrices, both before and during the sample preparation, and an awareness of the limitations of the chosen instrumental method of analysis.

Mass spectrometry (MS), infrared (IR) spectroscopy, and NMR spectroscopy with their numerous applications are the main instrumental techniques for the detection and identification of CWC-related chemicals. During the last few years, however, less laborious techniques such as LC and CZE have become attractive for the analysis of water samples and extracts where sample preparation is either not required or is relatively simple.

Sample preparation procedures and analytical techniques for the off-site laboratories of the CWC have been developed and tested in five international interlaboratory comparison (round-robin) tests,1–5 in two trial proficiency tests, and in three official proficiency tests (see Verification of Chemicals Related to the Chemical Weapons Convention). The ROPs for sampling and sample preparation6,7 were written and updated on the basis of the results of the round-robin tests. The ROPs (see Table 1) were designed to be comprehensive.
Fourier Transform Infrared in On-site and Off-site with minimum sample preparation by FTIR spectroscopy other approaches not excluded. ROPs should be used as first choice in the analysis, with sample preparation steps. It is also recommended that cals. Accordingly, some of the procedures contain many enough to allow the analysis of all CWC-related chemicals.

CWC-related chemicals in aqueous liquid samples (water samples) are usually recovered by extraction with organic solvent. Modern methods such as solid-phase extraction (SPE) and solid-phase microextraction (SPME) have also been presented. Organic extractions and these modern methods mainly recover nonpolar CWC-related chemicals, but leave behind the water-soluble and nonvolatile chemicals. These must also be recovered, however, because the agents tend to decompose (hydrolyze) rapidly under conditions in the environment. Techniques such as CZE and LC relying on element specific or mass spectrometric detection have been developed to provide easy and effective ways of recovering these chemicals from water samples with only minor sample preparation. For GC/MS analysis the water must be displaced and the analytes derivatized.

Soil samples have proved to be of critical importance in confirming the use of chemical warfare agents. Little has been published about the preparation of soil samples in the open literature, however. Usually the soil is extracted with organic solvent to recover the nonpolar CWC-related chemicals such as nerve and mustard agents and, in view of the probable degradation (hydrolysis), it

is also extracted with water to recover the water-soluble polar CWC-related chemicals.

The procedures used in off-site laboratories had to be modified for on-site use in order to reduce the amount and weight of solvents, reagents, and equipment. At present, three different procedures are being developed, tested, and validated for on-site inspections. The existing SOPs by no means cover all analytical tasks required in on-site situations, however, and method development and improvement are continuing.

Existing methods for the on-site analysis of CWC-related chemicals in environmental samples are based on GC/MS. Methods based on liquid chromatographic separation are not yet available. Before GC analysis, the chemicals must be extracted from the sample matrix. Volatile analytes can be extracted with organic solvents, concentrated, and then analyzed directly, whereas non-volatile and water-soluble or more polar analytes must be extracted with water or other polar solvent, the solvent evaporated, and the analytes derivatized.

This article covers the off-site and on-site sample preparation methods for analytical techniques used in off-site and on-site laboratories. The procedures described are from ROPs and from procedures followed at the Institute for the off-site methods and from the SOPs for the on-site methods. The usefulness of the methods as demonstrated in international comparison and proficiency tests is noted.

2 PREPARATION OF SAMPLES FOR OFF-SITE ANALYSIS

ROPs have been developed and validated for air, aqueous liquid (water), soil, wipe, active charcoal, concrete, paint, rubber, and other polymeric samples for off-site analysis.

2.1 Air Samples

It is recommended that the control zone and the collection zone of a XAD-2 tube be analyzed separately if the breakthrough volume of the most volatile chemicals of interest in the sampling conditions is not known. The control zone is removed from the tube to a small glass vial and sonicated with 2 mL of ethyl acetate for 3 min. The resin is filtered rapidly and the supernatant is analyzed. The trapped chemicals are desorbed from the collection zone by eluting 2 mL of ethyl acetate to the back end of the zone. (It is important to note that the elution direction should be opposite to the collection direction.) The eluate is collected in a glass vial under gravity.

If the breakthrough volume is known and was taken into account during sample collection, the whole tube can be eluted as described above for the collection zone. If required, the sample solutions can be concentrated under mild nitrogen flow. Care must be taken that the sample solutions are never concentrated to dryness because certain CWC-related chemicals are adsorbed firmly on to glass surfaces from residues of organic extracts.

It should be noted that highly volatile chemicals such as hydrogen cyanide (CAS 74-90-8) and phosgene (CAS 75-44-5) as well as polar water-soluble chemicals such as alkylphosphonic and alkylthiophosphonic acids, thiodiglycol (CAS 111-48-8), and aminoalcohols are not quantitatively trapped by XAD-2 resin.

Figure 1 Schematic presentation of the ROP for aqueous liquid sample preparation.
determined with a universal pH paper and, if necessary, the sample is neutralized with ammonium hydroxide or hydrochloric acid. The neutralized sample is liquid–liquid extracted with two portions of water-immiscible organic solvent using a 1:2 volume ratio of solvent to sample. Usually dichloromethane is used as extraction solvent and liquid–liquid extraction times are 2–5 min. The extracts are combined and dried. The dried extract is analyzed as such or, where necessary, after approximately 10-fold concentration with mild nitrogen flow. Concentration to dryness must be avoided because certain CWC-related chemicals are firmly adsorbed to glass surfaces from residues of organic extracts. This dichloromethane sample is analyzed for nonpolar CWC-related chemicals.

The aqueous fraction from the first extraction or another portion of the original sample is made alkaline with ammonium hydroxide and the same liquid–liquid extraction procedure is repeated (Figure 1, fraction 2A). This extract is analyzed after derivatization, for example, with 100µL of N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA, CAS 25561-30-2) for 1 mL extract. This sample is analyzed for alkaline CWC-related chemicals.

Alternatively (Figure 1, fractions 1B and 2B), both the neutralized and alkaline liquid–liquid extraction steps can be performed using Extrelut® (Merck) or another corresponding extraction cartridge under similar conditions to those of the liquid–liquid extraction. A portion of the sample is eluted into the cartridge and the analytes of interest are eluted from the sorbent with a suitable solvent (e.g. dichloromethane). The cartridges are used according to the instructions for use delivered by the cartridge manufacturer.

Further, a C18 SPE cartridge may be used (Figure 1, fraction 1C) instead of the neutralized liquid–liquid extraction step. A C18 cartridge (100 or 200 mg) is conditioned according to the instructions delivered by the manufacturer and a portion of the sample is eluted through the cartridge. Most of the water deposited in the cartridge is removed by sucking air through and, if necessary, interfering matrix components are removed by a wash solvent (e.g. water). Note that washing may also remove chemicals of interest. The cartridge is eluted with 2 mL of high-purity solvent (e.g. acetone). The eluate is dried, analyzed, and, if necessary, concentrated.

The aqueous fraction from the neutral or alkaline liquid–liquid extraction or another portion of the original sample is evaporated to dryness, but without cation exchange, as described above (Figure 1, fraction 4). The residue is dissolved in acetonitrile or other solvent suitable for silylation. BSTFA is added and the silylation is completed by heating the sample at 60°C for 30 min. The cooled sample is analyzed for polar CWC-related chemicals such as thioglycolic and aminoalcohols. Polar alkylphosphonic and alkylthiophosphonic acids can also be recovered from this fraction, but since the procedure does not contain a cation-exchange step, a large number of inorganic cations in the sample may mean that the recoveries of smaller acids such as methylphosphonic acid (CAS 993-13-5) are low, or the chemicals may not be recovered at all.

Methyl-N-tert(butyldimethylsilyl)trifluoroacetamide (MTBSTFA, CAS 77377-52-7) is another common silylation reagent used for CWC-related chemicals. BSTFA silylates the aminoalcohols such as triethanolamine (CAS 102-71-6) giving higher recoveries than MTBSTFA, but the tert-butyldimethylsilyl ethers formed when MTBSTFA is used are more stable than the trimethylsilyl ethers formed with BSTFA.

The aqueous fraction from the neutral or alkaline liquid–liquid extraction or another portion of the original sample is prepared for analysis of the sample for Lewisite 1 (CAS 541-25-3) and Lewisite oxide (CAS 3088-37-7) (Figure 1, fraction 5). The pH of the sample is adjusted with hydrochloric acid to pH 2, the sample is filtered, and 0.1 mL of freshly prepared solution containing 3,4-dimercaptotoluene (DMT, CAS 3088-37-2) 5 mg mL⁻¹ in acetone is added. The sample vial is shaken vigorously and allowed to stand for 10 min. One milliliter of n-hexane is added and the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water fraction is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

In addition, an appropriate portion of the aqueous liquid sample is filtered through a high-performance liquid chromatography (HPLC) filter and the filtrate is analyzed by LC/MS and CZE (Figure 1, fraction 6) and another portion is prepared for NMR analysis (fraction 7).

2.3 Soil Samples

If possible, the original sample is divided into four or more portions (1–10 g) for different analytical purposes, each placed in a screw-capped glass vial. One portion

CHEMICAL WEAPONS CHEMICALS ANALYSIS
of the soil (Figure 2, fraction 1) is extracted twice with dichloromethane by sonication, shaking, tumbling, or agitation for 10 min, each time using the same volume of water as the amount of the sample in milliliters (mL). The extracts are centrifuged, filtered, combined, and dried. The dried extract is analyzed as such or, where necessary, after approximately 10-fold concentration under mild nitrogen flow. Concentration to dryness must be avoided since certain CWC-related chemicals are firmly adsorbed to glass surfaces from residues of organic extracts. This sample is analyzed for nonpolar CWC-related chemicals.

A new portion of soil, or the soil fraction from the dichloromethane extraction (after drying in a fume cupboard for approximately 1 h), is extracted with distilled deionized water in the manner described above for the dichloromethane extract. Usually sonication is avoided because it may reduce recoveries of the polar CWC-related chemicals by creating new active sites for analytes in the soil. The extracts are centrifuged, filtered, and combined and the pH is determined.

An appropriate portion of the water extract (Figure 2, fraction 2) is eluted slowly through a conditioned SCX (100 or 200 mg) cation-exchange cartridge. The pH of the eluate is determined to test the completeness of the cation exchange and the eluate is evaporated to dryness on a rotary evaporator at 50 °C and 366 mPa. The residue is dissolved in dry acidic methanol and the solution is methylated with diazomethane. This sample is analyzed for polar alkylphosphonic and alkylthiophosphonic acids. Aminoalcohols remain in the SCX cartridge and cannot be recovered.

The extraction procedure with water is repeated, or another portion of a water extract is evaporated to dryness, but without cation exchange, as described above. The residue is dissolved in acetonitrile or other solvent suitable for silylation and silylated with BSTFA. The silylation is completed by heating the sample at 60 °C for 30 min (Figure 2, fraction 3). This sample is analyzed for polar CWC-related chemicals such as thioglycol and aminoalcohols. Polar alkylphosphonic and alkylthiophosphonic acids can also be recovered from this fraction, but since the procedure does not include a cation-exchange step, if there are large amounts of inorganic cations in the sample, the recoveries of smaller acids such as methylphosphonic acid may be low or they may not be recovered at all.

MTBSTFA is also commonly used as a silylation reagent for the CWC-related chemicals (see section 2.2).

Next, an appropriate portion of a water extract(s) is filtered through an HPLC filter and analyzed by LC/MS and CZE (Figure 2, fraction 4) and another portion is prepared for NMR analysis (fraction 5).

In the next step (Figure 2, fraction 6) a new portion of soil or the soil fraction from the water extraction step is extracted with 1% triethylamine (TEA, CAS 121-44-8) in methanol in the manner described above for dichloromethane. The centrifuged, filtered, and combined TEA/methanol extract is evaporated to dryness on a rotary evaporator at 50 °C and 31 Pa for ca. 10 min and then at 50 °C and 366 mPa for ca. 20 min. The evaporation residue is silylated as described above for the evaporation residue of the water extract. This sample is analyzed for alkaline CWC-related chemicals such as VX (CAS 50782-69-9).

Another sample portion, or the soil portion after dichloromethane extraction, is prepared for analysis of the sample for Lewisite 1 and Lewisite oxide (Figure 2, fraction 7). The soil is mixed with hydrochloric acid (e.g. 10 g of soil with ca. 15 mL of HCl). The pH of the water fraction is determined and adjusted to pH 2 if necessary. The pH of the water fraction must be maintained between 1.5 and 2.5 over a period of 30 min. The sample is then shaken vigorously for 30 s every 5 min for 60 min, allowed to settle for 1 h, centrifuged, and filtered. To the filtrate is added 0.1 mL of freshly prepared solution containing DMT 5 mg mL⁻¹ in acetone. The sample vial is shaken vigorously and allowed to stand for 10 min, and then

---

**Figure 2** Schematic presentation of the ROP for soil sample preparation.
1 mL of \( n \)-hexane is added and the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

### 2.4 Wipe Samples

The wipe sample is inserted into a glass vial or the original sample container is used as an extraction vessel. If blank sample is available, a small amount of this is tested for solubility in the selected solvent. Nonpolar organic solvent is poured over the sample. Acetone, ethyl acetate, dichloromethane, and deuterated chloroform (NMR analysis) are all good solvents. Care must be taken that the wipe sample is completely covered with the solvent. The mixture is sonicated for 3 min. The organic phase is quickly decanted and, if necessary, filtered and centrifuged. The extraction procedure is repeated with a second portion of the solvent. The extracts are combined and analyzed and, if necessary, an appropriate amount of the extract is concentrated approximately 10-fold with mild nitrogen flow. Concentration to dryness must be avoided since certain CWC-related chemicals are firmly adsorbed on to glass surfaces from residues of organic extracts (Figure 3, fraction 1). This extract is analyzed for nonpolar CWC-related chemicals. Since a wipe sample is not a very adsorptive sample matrix one can also expect to recover polar CWC-related chemicals and a 0.5–1 mL portion of the extract can be derivatized with 100 \( \mu \text{L} \) BSTFA for their analysis.

The wipe sample from the organic solvent extraction is then extracted with polar solvent (e.g. water, methanol, or acetonitrile) in a manner described above for nonpolar solvent (Figure 3, fraction 2A). For analysis with GC and GC hyphenated techniques, the polar extract must be derivatized. A part of the acetonitrile extract can be silylated with BSTFA in the same way as the organic extract of the wipe sample, although methanol or water extracts cannot be silylated directly and must first be evaporated to dryness. An appropriate part of the extract is evaporated to dryness on a rotary evaporator (water extract at 50 °C and 366 mPa for ca. 30 min and methanol extract at 50 °C and 31 Pa for ca. 10 min followed at 50 °C and 366 mPa for ca. 20 min). The methanol extract can also be evaporated under mild nitrogen flow. Over the evaporation residue 0.5 mL of acetonitrile and 0.5 mL of BSTFA are added and the silylation mixture is heated at 60 °C for 30 min to complete the silylation. This sample is analyzed for polar CWC-related chemicals such as thioglycol, aminoalcohols, and polar alkylphosphonic and alkylthiophosphonic acids.

A suitable portion of a water, methanol, or acetonitrile extract can also be analyzed by LC/MS or CZE after filtration through a HPLC filter (Figure 3, fraction 2B), and another portion can be prepared for NMR analysis (fraction 2C).

An appropriate portion of the polar extract of the wipe sample is prepared for analysis of the sample for Lewisite 1 and Lewisite oxide (Figure 3, fraction 2D). The pH of the sample is adjusted with hydrochloric acid to pH 2, the sample is filtered, and 0.1 mL of freshly prepared solution containing DMT 5 mg mL\(^{-1}\) in acetone is added. The sample vial is shaken vigorously and allowed to stand for 10 min, 1 mL of \( n \)-hexane is added, and the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

### 2.5 Active Charcoal Samples

Active charcoal sometimes is doped with various chemicals to modify its properties for a specific purpose. This
may cause degradation of the sample chemicals and extraction problems. The matrix may also contain substantial amounts of water. For these reasons the origin and background of active charcoal samples should always be ascertained.

The active charcoal material is placed in a glass vial. The extraction solvent is added (twice the volume of the charcoal) and the mixture is sonicated for 3 min. Suitable solvents are acetone, dichloromethane, carbon disulfide, and deuterated chloroform (for NMR analysis). The organic phase is quickly decanted and, if necessary, filtered and centrifuged. The extracts are analyzed and, if necessary, an appropriate amount of the extract is concentrated approximately 10-fold with mild nitrogen flow.

The sample or a few grains of it can also be analyzed by thermal desorption (see Gas Chromatography in Screening of Chemicals Related to the Chemical Weapons Convention) if the origin and nature of the charcoal material and the sampling procedure are known.

2.6 Concrete Samples

Small pieces of a concrete sample may be extracted as such, but if the sample pieces are large, homogenizing by crushing will be necessary before extraction. A piece of concrete (ca. 10 g) is inserted into a glass bottle, 10 mL of acetone or dichloromethane is added, and the sample mixture is sonicated for 30 min (Figure 4, fraction 1). More solvent must be used if the sample is not covered by the solvent. To keep the bath at ambient temperature, the temperature of the water bath is monitored and water is added, if necessary. The organic phase is quickly decanted and, if necessary, centrifuged and filtered. The extraction procedure is repeated with a second portion of the solvent. The extracts are combined and analyzed and, if necessary, an appropriate amount of the extract is concentrated approximately 10-fold under mild nitrogen flow. Concentration to dryness must be avoided since certain CWC-related chemicals are firmly adsorbed to glass surfaces from residues of organic extracts. This extract is analyzed for nonpolar CWC-related chemicals.

The concrete sample from the organic extraction or a new portion of 10 g of the original sample is then extracted with distilled, deionized water in the manner described above for organic solvent (Figure 4, fraction 2). This sample is analyzed for polar CWC-related chemicals such as thiodiglycol, aminoalcohols, and polar alkylphosphonic and alkylthiophosphonic acids. The evaporation residue may also be methylated instead: the residue is dissolved in dry acidic methanol and the solution is methylated with diazomethane. This sample is analyzed for polar alkylphosphonic and alkylthiophosphonic acids.

A suitable portion of the water extract can be analyzed by LC/MS or CZE after filtration through a HPLC filter (Figure 4, fraction 2B) and another portion can be prepared for NMR analysis (fraction 2C).

The concrete sample from the water extraction or a new portion of 10 g of the original sample is then extracted in a similar way with 1 M HCl solution (Figure 4, fraction 3A). This extract is handled in the same way as the water extract, for the same analytes. Note that silylation of acidic evaporation residues may be difficult and neutralization of the extract before evaporation to dryness is recommended.

Figure 4 Schematic presentation of the ROP for concrete sample preparation.
if the HCl extract is to be silylated to recover chemicals such as thiodiglycol and aminoalcohols.

An appropriate portion of the HCl extract of the concrete sample is prepared for analysis of the sample for Lewisite 1 and Lewisite oxide (Figure 4, fraction 3B). The pH of the sample is adjusted with hydrochloric acid to pH 2, the sample is filtered, and 0.1 mL of freshly prepared solution containing DMT 5 mg mL\(^{-1}\) in acetone is added. The sample vial is shaken vigorously and then allowed to stand for 10 min. After addition of 1 mL of \(n\)-hexane the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

### 2.7 Paint, Rubber, and other Polymeric Samples

The sample is crushed or cut into small pieces, if necessary, and placed into a glass bottle. Then 10 mL of acetone (dichloromethane, acetone-\(d_6\), or CDCl\(_3\)) is added and the sample mixture is sonicated for 10 min (Figure 5, fraction 1). Solvent must be sufficient to cover the sample. Some paint, rubber, and polymeric matrices may, however, be soluble in or swell in dichloromethane or chloroform and the solubility of the sample in the extraction solvent should be tested before the solvent is used, especially if a blank sample is available. The organic phase is quickly decanted and, if necessary, centrifuged and filtered. The extraction procedure is repeated with an additional portion of the solvent. The extracts are combined and analyzed and, if necessary, an appropriate amount of the extract is concentrated approximately 10-fold under mild nitrogen flow. Concentration to dryness must be avoided since certain CWC-related chemicals are firmly adsorbed on to glass surfaces from residues of organic extracts. This extract is analyzed for nonpolar CWC-related chemicals. Paint, rubber, and other polymeric samples are not very adsorptive sample matrices. For this reason one could also expect to recover some polar CWC-related chemicals from this fraction. To find these, a portion of 0.5–1 mL of the extract can be derivatized with 100 \(\mu\)L of BSTFA.

The paint, rubber, or other polymeric sample from the organic extraction, or a new portion of the original sample is extracted with distilled deionized water in the manner described above for organic solvent (Figure 5, fraction 2). This sample is analyzed for polar CWC-related chemicals. For analysis with GC and GC hyphenated techniques the polar extract must first be derivatized: an appropriate part of the extract is evaporated to dryness on a rotary evaporator at 50 °C and 366 mPa for ca. 30 min. Then 0.5 mL of acetonitrile and 0.5 mL of BSTFA are poured over the evaporation residue and the silylation mixture is heated at 60 °C for 30 min to complete the silylation (fraction 2A). This sample is analyzed for polar CWC-related chemicals such as thiodiglycol, aminoalcohols, and polar alkylphosphonic and alkylthiophosphonic acids. The evaporation residue may also be methylated: the residue is dissolved in dry acidic methanol and the solution is methylated with diazomethane. This sample is analyzed for polar alkylphosphonic and alkylthiophosphonic acids.

A suitable portion of the water extract can be analyzed by LC/MS or CZE after filtration through a HPLC filter (Figure 5, fraction 2B) and another portion can be prepared for NMR analysis (fraction 2C).

Another suitable portion of the water extract is prepared for analysis of the sample for Lewisite 1 and Lewisite oxide (Figure 5, fraction 2D). The pH of the sample is adjusted with hydrochloric acid to pH 2, the sample is filtered, and 0.1 mL of freshly prepared solution containing DMT 5 mg mL\(^{-1}\) in acetone is added. The sample vial is shaken vigorously and allowed to stand for 10 min. After 1 mL of \(n\)-hexane is added the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.
3 PREPARATION OF SAMPLES FOR ON-SITE ANALYSIS

To date, SOPs have been developed and validated for on-site analysis of aqueous liquid (water), soil, and wipe samples.\(^{[31]}\) Method development for other matrices such as air and improvement of the existing methods are continuing.

3.1 Aqueous Liquid Samples

A 10 mL portion of aqueous liquid is taken into a screw-capped vial. The pH of the sample is determined with a universal pH paper and, if necessary, the sample is neutralized with ammonium hydroxide or hydrochloric acid. The sample is extracted twice with 5 mL of dichloromethane, with shaking. The dichloromethane extracts are combined and, after drying, 1 mL of the extract is set aside for GC/MS analysis as such, and the rest is concentrated approximately 10-fold with mild nitrogen flow and analyzed (Figure 6, fraction 1). These dichloromethane samples are analyzed for nonpolar CWC-related chemicals.

The aqueous fraction remaining after dichloromethane extraction is divided into two equal portions. One portion (Figure 6, fraction 2A) is evaporated to dryness in a centrifugal evaporator, 0.5 mL of acetonitrile and 0.5 mL of BSTFA are added to the evaporation tube, and the silylation mixture is heated at 60 °C for 30 min to complete the silylation. This sample is analyzed for polar CWC-related chemicals such as thiodiglycol and aminoalcohols.

The other portion of the aqueous fraction (Figure 6, fraction 2B) is eluted slowly through a conditioned SCX (500 mg) cation-exchange cartridge. The pH of the eluate is determined to test the completeness of the cation exchange and, if necessary, the eluate is neutralized. The neutral eluate is evaporated and silylated as described above for the first aqueous portion. This sample is analyzed for polar alkylphosphonic and alkylthiophosphonic acids. Aminoalcohols remain in the SCX cartridge and cannot be recovered from this sample.

An optional SPE procedure (Figure 6, fraction 2C) for aqueous samples is included in the SOPs for on-site analysis. The pH of a 5 mL portion of the aqueous fraction is adjusted with hydrochloric acid and ammonium hydroxide to pH 4.5. The sample is eluted slowly through a conditioned SCX (500 mg) cation-exchange cartridge and after that through a conditioned NH\(_2\) (100 mg) anion-exchange cartridge. The retained analytes are eluted slowly from the NH\(_2\) cartridge with 2 mL of 2% hydrochloric acid in methanol. The eluate is adjusted to pH 8 with concentrated ammonia and then evaporated to dryness with mild nitrogen flow. The evaporation residue is silylated as described above for the first aqueous portion to provide the sample in a form suitable for GC/MS analysis. Aminoalcohols remain in the SCX cartridge and cannot be recovered from this sample. This method was developed for analysis of samples for polar alkylphosphonic and alkylthiophosphonic acids. The effectiveness of the method varies very much with the sample matrix, however. Depending, among other things, on the capacity and quality of the cation- and anion-exchange cartridges and the amount and character of impurities in the sample, the recovery values for alkylphosphonic and alkylthiophosphonic acids may be very low. Accordingly, this method should be considered as an optional technique only for sample matrices of known ion content.

A new sample portion of 10 mL is prepared for analysis of the sample for Lewisite 1 and Lewisite oxide (Figure 6, fraction 3). The pH of the sample is adjusted with hydrochloric acid to pH 2, the sample is filtered, and 0.1 mL of freshly prepared solution containing DMT 5 mg mL\(^{-1}\) in acetone is added. The sample vial is

---

Figure 6 Schematic presentation of the SOP for aqueous liquid sample preparation.
shaken vigorously and allowed to stand for 10 min. One milliliter of n-hexane is added and the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

3.2 Soil Samples

A 5 g portion of soil is extracted with 5 mL of dichloromethane by shaking manually for 1 min. The extract is centrifuged and filtered and the extraction procedure is repeated with an additional 5 mL of dichloromethane. The extracts are combined and dried. One milliliter of the dried extract is set aside for GC/MS analysis as such and 3 mL is concentrated approximately 10-fold under mild nitrogen flow and analyzed (Figure 7, fraction 1). These dichloromethane samples are analyzed for nonpolar CWC-related chemicals.

The soil sample from the dichloromethane extraction is placed in a fume cupboard and allowed to dry for approximately 1 h. The sample is then extracted twice with 5 mL of distilled deionized water in the manner described above for dichloromethane. The centrifuged, filtered, and combined water extract is divided into two equal portions (Figure 7, fraction 2).

The first portion (Figure 7, fraction 2A) is evaporated to dryness in a centrifugal evaporator, 0.5 mL of acetonitrile and 0.5 mL of BSTFA are added to the evaporation tube, and the silylation mixture is heated at 60°C for 30 min to complete the silylation. This sample is analyzed for polar CWC-related chemicals such as thiodiglycol and aminoalcohols.

The other portion (Figure 7, fraction 2B) of the water extract is eluted slowly through a conditioned SCX (500 mg) cation-exchange cartridge. The pH of the eluate is determined to test the completeness of the cation exchange and, if necessary, the eluate is neutralized. The neutral eluate is evaporated and silylated as described above for the first aqueous portion. This sample is analyzed for polar alkylphosphonic and alkylthiophosphonic acids. Aminoalcohols remain in the SCX cartridge and cannot be recovered.

An optional SPE procedure (Figure 7, fraction 2C) for the water extract can be applied. The pH of a 5 mL portion of the water extract is adjusted with hydrochloric acid and ammonium hydroxide to pH 4.5. The sample is eluted slowly through a conditioned SCX (500 mg) cation-exchange cartridge and after that through a conditioned NH2 (100 mg) anion-exchange cartridge. The retained analytes are eluted slowly from the NH2 cartridge with 2 mL of 2% hydrochloric acid in methanol. The eluate is adjusted to pH 8 with concentrated ammonia and then evaporated to dryness under mild nitrogen flow. The evaporation residue is silylated as described above for the first aqueous portion, to provide the sample in a form suitable for GC/MS analysis. Aminoalcohols remain in the SCX cartridge and cannot be recovered from this sample. This method was developed for analysis of samples for polar alkylphosphonic and alkylthiophosphonic acids. The effectiveness of the method varies very much with the sample matrix, however. Depending, among other things, on the capacity and quality of the cation- and anion-exchange cartridges and the amount and character of impurities in the sample, the recoveries of alkylphosphonic and alkylthiophosphonic acids may be very low. Accordingly, this method should be considered as an optional technique only for sample matrices of known ion content.

In the next step (Figure 7, fraction 3) a new 5 g portion of the soil is extracted with 5 mL of 1% TEA in methanol as described above for dichloromethane. Under mild nitrogen flow at 30°C 4 mL of the centrifuged, filtered, and combined TEA/methanol extract is evaporated to dryness. The evaporation residue is silylated in the manner described above for the evaporation residue of the water extract. This sample is analyzed for alkaline CWC-related chemicals such as VX.

Another new sample portion of 5 g is prepared for analysis of the sample for Lewisite 1 and Lewisite oxide.
SAMPLE PREPARATION FOR ANALYSIS OF CWC-RELATED CHEMICALS

11

(Figure 7, fraction 4). The soil is mixed with 15 mL of hydrochloric acid (pH 2). The pH of the water fraction is determined and, if necessary, adjusted to pH 2. The pH of the water fraction must be maintained between 1.5 and 2.5 over a period of 30 min. The sample is then shaken vigorously for 30 s every 5 min for 60 min, allowed to settle for 1 h, centrifuged, and filtered. To the filtered extract is added 0.1 mL of the freshly prepared solution containing DMT 5 mg mL⁻¹ in acetone. The sample vial is shaken vigorously and allowed to stand for 10 min, 1 mL of n-hexane is added, and the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane–water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

### 3.3 Wipe Samples

The wipe sample is inserted into a glass vial and approximately 10 mL of dichloromethane is added. Care must be taken that the wipe is completely covered by the solvent. The sample is shaken for 1 min. The organic phase is quickly decanted and filtered, and the extraction procedure is repeated with an additional 10 mL of dichloromethane. The extracts are combined and dried. Under mild nitrogen flow, 2 mL of the dried extract is concentrated approximately 10-fold and analyzed (Figure 8, fraction 1). These dichloromethane extracts are analyzed for nonpolar CWC-related chemicals.

Next the wipe sample from the dichloromethane extraction is placed in a fume cupboard and allowed to dry for approximately 1 h. About 12 mL of distilled, deionized water is added, with care taken that the wipe is completely covered by the solvent. The sample is shaken for 1 min. The wipe is then extracted, in the manner described above for dichloromethane. The centrifuged, filtered, and combined water extract is divided into two portions of 3 mL each (Figure 8, fraction 2).

The first portion (Figure 8, fraction 2A) is evaporated to dryness in a centrifugal evaporator. Added to the evaporation tube are 0.5 mL of acetonitrile and 0.5 mL of BSTFA and the silylation mixture is heated at 60 °C for 30 min to complete the silylation. This sample is analyzed for polar CWC-related chemicals such as alkylphosphonic and alkylthiophosphonic acids, thiodiglycol, and aminoalcohols. An optional SPE procedure for the water extract can be applied (Figure 8, fraction 2B). The pH of a 3 mL portion of the water extract is adjusted with hydrochloric acid and ammonium hydroxide to pH 4.5. The sample is eluted slowly through a conditioned SCX (500 mg) cation-exchange cartridge and after that through a conditioned NH₂ (100 mg) anion-exchange cartridge. The retained analytes are eluted slowly from the NH₂ cartridge with 2 mL of 2% hydrochloric acid in methanol. The eluate is adjusted to pH 8 with concentrated ammonia and then evaporated to dryness under mild nitrogen flow. The evaporation residue is silylated as described above for the first aqueous portion to provide the sample in a form suitable for GC/MS analysis. Aminoalcohols remain in the SCX cartridge and cannot be recovered from this sample. This method was developed for analysis of samples for polar alkylphosphonic and alkylthiophosphonic acids. The effectiveness of the method varies very much with the sample matrix, however. Depending, among other things, on the capacity and quality of the cation- and anion-exchange cartridges and the amount and character of impurities in the sample, the recovery values for alkylphosphonic and alkylthiophosphonic acids may be very low. Accordingly, this method should be considered as an optional technique only for sample matrices of known ion content.

The second portion of 3 mL is prepared for analysis of the samples for Lewisite 1 and Lewisite oxide (Figure 8, fraction 2C).
fraction 2C). The pH of the sample is adjusted with hydrochloric acid to pH 2, the sample is filtered, and 0.1 mL of freshly prepared solution containing DMT 5 mg mL⁻¹ in acetone is added. The sample vial is shaken vigorously and allowed to stand for 10 min. Then 1 mL of n-hexane is added and the sample is shaken vigorously for 30 s every 10 min for 30 min. The hexane fraction is allowed to separate. The top hexane-water layer is transferred to a new vial and centrifuged. After centrifugation the hexane fraction is separated, dried, and submitted for analysis.

4 QUALITY CONTROL

Ensuring quality during sample preparation requires that the samples do not come in contact with one another, are not mixed with one another, nor are they contaminated by chemicals from the laboratory or other samples, and that the procedures are shown to be controlled.

Meeting the quality demands of sample preparation requires that the ROPs or SOPs are followed in all sample preparations. The purity of solvents and reagents is checked before sample preparation by the same methods used for analysis. The purity of 10-fold concentrated solvents is also tested beforehand. The background generated during the sample preparation procedure is demonstrated by preparing a blind sample, and by passing the same solvents, same reagents, and similar glassware used in sample preparation through the whole procedure. Similarly, where possible the background generated by the sample matrix is demonstrated by passing a blank sample through the entire procedure.

It cannot be emphasized too strongly that mistakes in sample preparation may cause failure of the whole analytical procedure, even with the most sophisticated instrumentation. This means that not only must the QC rules be followed but work must be done unhurriedly and with total concentration.

5 SAFETY

CWC-related chemicals must be handled with great care. Persons handling toxic chemicals must be specially trained for the work. When toxic samples are handled, decontamination solution, protective masks, and autoinjectors of nerve agent antidotes must always be available, and no one must ever work alone. Individual protective gear such as a laboratory coat, chemically resistant protective gloves, and safety goggles are essential during sample preparation. Toxic samples must always be prepared in a fume cupboard.

The fume cupboard is cleaned directly after sample preparation. Any samples, organic solvent waste, chlorinated solvent waste, and aqueous wastes which do not require decontamination are collected into separate clearly marked waste containers. In the same way paper and consumable wastes which do not require decontamination are collected in a clearly marked waste box. Materials requiring decontamination must be treated with a proper decontamination solution and disposed of in designated waste containers. Glassware and accessories are flushed with decontamination solution and soaked in potassium hydroxide solution and, if not destroyed, they are washed with alkaline nonphosphorus detergent before further cleaning.

6 INTERNATIONAL COMPARISON AND PROFICIENCY TESTS

As described in the Introduction of this article, sample preparation procedures for off-site laboratories for the CWC have been developed and tested in five international interlaboratory comparison (round-robin) tests,¹⁻⁵ in two trial proficiency tests, and in four official proficiency tests (see Verification of Chemicals Related to the Chemical Weapons Convention). Table 3 lists the types of samples in these tests. The first three tests were arranged mainly for purposes of method development, the fourth and fifth also for testing and validating of methods. The reports describing these tests (the round-robin books) contain a thorough description of how each of the participating laboratories prepared their samples.¹⁻⁵

Only in one test (the fourth round-robin) were the identified chemicals quantified,⁴ and then only to facilitate the evaluation of sample preparation methods. The quantitative results varied widely. Weaknesses were revealed in the procedures because all the chemicals were polar and adsorptive. Comparison of the quantitative results as a means of deciding upon the best sample preparation procedures proved to be an unreasonable approach, however, as the total variance in the results was clearly the product of several factors: the sample preparation procedure, the quantitative method, and the instrumental technique. Nevertheless, the exercise proved to have considerable educational value. The test revealed weaknesses in the existing ROPs⁶ and the methods were subsequently improved to cover the gaps.⁷

In both the trial and official proficiency tests, the ROPs for sample preparation validated in the round-robin tests proved to be useful methods for recovering CWC-related chemicals spiked at trace level. The participating laboratories had prepared the samples following the ROPs, although sometimes with slight modifications. Many of
Table 3  Sample types in the international interlaboratory comparison (round-robin) tests for verification of chemical disarmament held for method development and testing, and in trial and official proficiency tests held for selection of designated laboratories

</table>
| the laboratories were also able to identify degradation products or impurities of the spiking chemicals present in only very low concentration. The results show that the ROPs work well in the recovery of chemicals. Where a laboratory had problems the most common difficulty was the unsuccessful identification of the spiking chemicals or lack of reference data, not improper sample preparation. An essential requirement for achieving good analytical results is the experience and knowledge of CWC-related chemicals of those workers doing the sample preparation and instrumental analysis. Some examples of incorrect sample preparation revealed in the evaluation of results of the proficiency tests are noted in the following.

In the first trial proficiency test one laboratory did not find either of the spiking chemicals, sesquimustard (CAS 3563-36-8) and CR (CAS 257-07-8), in a paint sample. The laboratory scratched the paint away from the paint plate surface before extraction, which may have caused the chemicals of interest to escape. Furthermore, the matrix probably dissolved during the extraction, making the analysis of the extract, with so much interference from the sample matrix, more difficult.

In the second trial proficiency test one laboratory failed to find methylphosphonic acid and cyclopentyl methylphosphonate (CAS 73207-99-5) in a water sample. The laboratory evidently did not evaporate a portion of the water sample to dryness and derivatize the
evaporation residue, but only derivatized a portion of an alkaline dichloromethane extract. Since the spiking chemicals are polar and acidic they are not extractable into a nonpolar solvent under alkaline conditions.

The soil sample was even more problematic in this test. Only six of the 15 participating laboratories successfully identified both N,N-diethylenoethanol (CAS 100-37-8) and N-ethylidienolamine (CAS 139-87-7). For these particular spiking chemicals, efficient TEA/methanol extraction followed by a silylation procedure was essential in the sample preparation. One laboratory missed both spiking chemicals, probably because the TEA/methanol extraction was not carried out. Another laboratory also missed them but for another reason. Instead of TEA, ethyldimethylamine (EDMA, CAS 598-56-1) was used as extractant, and although this should not have had a dramatic effect on the recoveries of the spiking chemicals since EDMA should be as good a modifier as TEA, the laboratory then derivatized the 1% EDMA/methanol extract with BSTFA, thus removing any chance of success. Chemicals in alcohol solutions cannot be silylated, and this must have been the reason why the spiking chemicals were not found.

In the first official proficiency test, two laboratories did not evaporate and derivatize the evaporation residue of a water sample and failed to identify n-propylphosphonic acid (PPA, CAS 4672-38-2). One laboratory employed a SPE method but used a strong cation-exchange cartridge SAX. Weak anion-exchange cartridges are recommended for the SPE method to ensure recovery of the acidic degradation products from water samples. Acids such as PPA are strongly retained on strong anion-exchange cartridges and hence difficult to elute from the cartridge.

3,3-Dimethyl-2-butanol (DMB, CAS 464-07-03) was another spiking chemical in the water sample in this test. One laboratory missed it because of insufficient sample preparation: the water sample was not extracted with dichloromethane in which the chemical is soluble, but was merely evaporated and derivatized. DMB was evaporated together with the water and in this way was lost.

In the third official proficiency test at least four laboratories failed to find (1-methylethyl)phosphonic acid (IPPA, CAS 4721-37-3) most probably because the water extract was not prepared properly. These laboratories proceeded to neutral and alkaline dichloromethane extraction and some even evaporated the water to dryness. However, recovery of IPPA requires direct analysis of the water sample by LC/MS (or CZE) or else cation exchange, evaporation of the sample to dryness, and derivatization (methylation) of the residue.

In the fourth official proficiency test two laboratories failed to find propyl propylphosphonate (CAS 21921-97-1) and O-propyl propylthiophosphonate (CAS unknown) in the water sample. The laboratories followed the ROPs but with slight modifications. One laboratory cation exchanged a portion of the water sample, and after evaporating it to dryness, silylated the residue with 1% tert-butyldimethylchlorosilane (CAS 18162-48-6)/MTBSTFA (10%) in toluene. The other laboratory extracted a portion of the water sample with dichloromethane, evaporated the water phase to dryness, and dissolved the evaporation residue in diazomethane/ether solution. Another portion of the water sample was extracted with ethyl acetate and evaporated to dryness and the evaporation residue was dissolved in acetone. The acetone solution was then itself evaporated to dryness and silylated with BSTFA/pyridine in acetonitrile. Yet a third portion of the water sample was adjusted to the same pH as the blank water sample and extracted with dichloromethane. After that the pH was reduced to ca. 2.5 and the dichloromethane extraction was repeated. This acidic dichloromethane was dried, filtered, and evaporated to dryness before silylation with BSTFA/pyridine in acetonitrile.

It should have been possible to identify the two spiking chemicals in the cation-exchanged and silylated water fraction. However, following cation exchange, higher recoveries are usually obtained for alkyl phosphonates and alkylthiophosphonates if methylation is used for derivatization. Moreover, the solubility of these chemicals in the silylation mixture is critical for their recovery and therefore either acetonitrile or tetrahydrofuran is typically used as a silylation solvent. The solubility of the spiking chemicals in toluene, which the first laboratory chose as silylation solvent, perhaps was not sufficient. The second laboratory dissolved the first evaporation residue in diazomethane/ether solution, but perhaps the solubility of the spiking chemicals in ether was not sufficient either, especially since the water was not cation exchanged before evaporation. Similarly, before silylation the second sample fraction was not cation exchanged, and the evaporation residue was dissolved in acetone in which the spiking chemicals are only sparingly soluble. Small amounts of these types of spiking chemicals should be recovered in acidic dichloromethane extracts that are derivatized as such. However, the laboratory first evaporated the dichloromethane extracts to dryness and then silylated the evaporation residue. This might have caused loss of the spiking chemicals.

ACKNOWLEDGMENTS

My thanks to Olli Kostiainen, Otto Ahonen, Markku Mesilaakso, Marja-Leena Rapinoja, and Professor Marjatta Rautio of the Institute for their helpful comments.
and to Harri Kiljunen for his assistance with computer programs during preparation of the manuscript. Seija Lemettinen and Kirsi Rosendahl provided excellent technical assistance during the round-robin and proficiency tests, and Marja-Leena Rapinoja during the validation of on-site sample preparation methods, and to them my thanks as well.

I am grateful to Dr. Kathleen Ahonen for improving the language of the manuscript.

1 INTRODUCTION
1.1 The Chemical Weapons Convention

The Chemical Weapons Convention (CWC), which entered into force on April 29, 1997, prohibits the development, production, stockpiling and use of chemical weapons (CW). It is administered by the Organization for the Prohibition of Chemical Weapons (OPCW), which is based in The Hague. The CWC centers on a general purpose criterion which stipulates that toxic chemicals and their precursors may only be developed, produced, acquired, retained, transferred or used for permitted purposes and in types and quantities consistent with such purposes. In addition to provisions for one State Party to call for a challenge inspection against another suspected of contravening the convention, there are declaration, routine inspection and transfer obligations for specified chemicals that pose particular risks. These chemicals are grouped in three schedules. Schedule 1 contains toxic chemicals which are a high risk to the convention; they are mainly nerve agents and mustards. Schedule 2 contains industrial chemicals which are a significant risk; these include chemicals that could be used in CW, such as the pesticide amiton, and also precursors to the chemicals in Schedule 1. Schedule 3 contains more widely used industrial chemicals such as phosgene, and precursors to some Schedule 1 or 2 chemicals. In addition to the routine inspections of facilities producing Schedule 1, 2 or 3 chemicals, there are provisions for inspecting old or abandoned CW sites, and production, storage and destruction facilities. This allows the OPCW to monitor the destruction of facilities and weapons by the small number of States Parties who are declared CWC-related chemical possessors. During the course of inspections, whether routine or challenge, there may be a requirement for the inspection team (IT) to investigate unresolved ambiguities. The IT has the right to request clarification, and if ambiguities cannot be clarified by negotiation then samples may be taken for analysis.

Example of sampling equipment, procedures and sample management techniques are described, together with a brief description of screening and detection. Some analyses may be performed on-site by the inspectors, using equipment they bring with them, but for more difficult questions it may be necessary to remove a sample for analysis on an anonymous basis in two or more of a global network of laboratories “designated” by the OPCW. The end result of any sampling and analysis operation must be able to stand up to international scrutiny, and therefore chain-of-custody or audit-trail procedures must be strictly followed. The process should allow the re-creation of the position or state of the sample at any time during the handling of the sample from cradle to grave.
CHEMICAL WEAPONS CHEMICALS ANALYSIS

for sampling and analysis are laid down in the OPCW inspection manual. These procedures were developed by technical experts of the States Parties, working in expert and task force groups before entry into force (EIF) of the CWC. Some analyses may be performed on-site by the inspectors using equipment they take with them, but for more difficult questions it may be necessary to remove a sample for analysis on an anonymous basis in two or more of a global network of laboratories designated by the OPCW. The end result of any sampling and analysis operation must be able to stand up to international scrutiny, and therefore OPCW-designated laboratories must have achieved accreditation by a recognized body and must also pass proficiency tests organized regularly by the OPCW.

1.2 Sampling, Detection and Screening
There is an inter-relationship and synergism associated with the three elements of sampling, detection and screening in the investigation of sites which are either contaminated with CWC-related chemicals or thought to contain munitions or other materials of concern to the CWC. These three elements in combination are essential for the safe and accurate assessment of CWC-related chemical sites. Screening a site with the appropriate detection equipment is useful both for the safe conduct of a sampling mission and for verification purposes. In the safety role the use of detectors will greatly assist the safe progress of the sampling mission, by determining the level of protection to be used during both the reconnaissance and sampling processes. In the verification role detectors can be used to screen the areas of concern and pinpoint chemical contamination for subsequent sampling. Generally methods of detection should be sensitive and discriminating, and should support the sampling and analysis process but not supersede it.

2 SAMPLING

2.1 Elements of a Sample Plan
Few reference books offer guidelines for the collection of samples that have relevance to CW. Therefore, to aid the planning of missions to CW sites, one must look to the area of environmental sampling for assistance. The Royal Society of Chemistry and the American Chemical Society have produced guidelines for the sampling process which are equally relevant in the CW field.\(^1\) There is a need to define the objective/aims of the measurement;\(^2\) the selection of constituents (analytes) and analytical methods;\(^3\) the determination of sampling locations;\(^3\) the determination of sample types and methods of sampling;\(^3\) the selection of methods for sample preservation, transport and protection from the possibility of tampering;\(^3\) the preparation of the final plan (protocol);\(^3\) and the revision in the light of experience.\(^3\)

The above summary of factors to be considered when designing a sampling plan is reproduced by permission of the Royal Society of Chemistry.

2.2 Factors Influencing a Sampling Plan
When assembling a sampling plan the following factors need to be considered.

- Preinspection planning should be carried out before embarking on any sampling mission. The following information can be useful in formulating an initial plan:
  - preinspection knowledge, e.g. geographical, meteorological and intelligence;
  - construction plans of the facility, if available;
  - local knowledge from present or former workers at the site;
  - intelligence reports from the area (this is especially important in an “alleged use” scenario);
  - historical documentation from government agencies;
  - aerial/satellite photographs.

- The availability and suitability of detection equipment for on-site safety and screening purposes should be considered.
- Safety/risk management, and formulation of a safety plan that takes into account chemical and physical hazards, are essential for the safe completion of the mission. The IT should be fully aware of the toxicological properties of all expected hazards, and be trained to operate in a contaminated environment.
- When defining a chemical hazard under the CWC a “chemical weapon” is stated in Article II of the convention as:
Physical hazards and specific site concerns which may cause problems to the samplers include the following:

- the possibility of site contamination and the associated decontamination problems this presents;
- the possibility of explosive or fire hazards from the use of electrical equipment in hazardous environments;
- the problem of site safety in terms of unsafe structures, for example old or semidemolished buildings, underground facilities, complicated chemical plant, storage bunkers, flooding;
- availability of resources, e.g. power, water, shelter, communications;
- environment/terrain, accessibility;
- military activity of a hostile nature, especially when dealing with alleged use incidents.

Arrangements for medical backup should be as follows:

- the IT must be sure adequate medical safety measures are in place;
- medical facilities of an adequate nature should either be available on-site or a medical team should be present as a subunit of the IT;
- real-time monitoring for toxic chemicals should be available if necessary (this would perhaps be dealt with in the site risk assessment and any precautionary monitoring initiated as soon as the IT reaches the site).

- Selection of sampling equipment will be determined by types and numbers of samples and will vary according to the inspection. Once on-site the team may be isolated and therefore initial planning and selection of sufficient and suitable sampling equipment will be essential to the successful completion of the mission.
- Availability of personal protective equipment (PPE); the type of equipment needed will be determined by the expected hazard. A preinspection assessment of the hazards to be encountered will be needed and will rely upon knowledge of the site gained prior to departure. Without this information it will be necessary to take the fullest protection possible, although this may severely affect the logistical requirements of the mission and hamper the sampling team in the execution of its remit. The IT should be fully trained and familiar with the operation and use of all equipment provided for the safe execution of their duties.
- Arrangements for decontamination and waste management may be available locally. If not, the team will need to cater for both expected and unexpected hazards, and suitable equipment will need to accompany the team. All sampling activities produce waste and therefore the sampling plan should cater for the decontamination and disposal of all waste created during the mission.
- On-site planning will involve adaptation of the sampling plan to suit the on-site conditions. For example, a statistical approach to sampling may be necessary to identify suitable sampling points where no obvious areas are immediately apparent.

2.3 Sample Collection

When considering the special requirements involved in the collection of samples from a site believed to be contaminated with CWC-related chemicals, there are very few reference textbooks to consult for advice. The equipment used and procedures followed by an OPCW IT for sampling and analysis have been laid down in the draft OPCW inspection manual. These recommended operating procedures (ROPs) and sampling kits were initially drawn up by technical experts of the States
Parties, working in expert and task force groups before EIF, and since then modifications and additions have been made in the light of experience. Similarly, there are procedures and equipment lists in the NATO (North Atlantic Treaty Organization) Handbook, AEP-10, which contains procedures to follow in the event of CW usage in the battlefield, and in the Finnish “Blue Book”, which contains ROPs for sampling and analysis in the verification of chemical disarmament.1(4,5)

Locations from which neat chemical samples may be collected include munition bunkers, intact munitions, chemical plant, reactors and process/filling lines. Other areas from which environmental samples will be taken include waste outflows, waste treatment or storage areas, burning/demolition grounds, trials areas, vehicle tyres, flooring in storage areas, reactor flanges, ventilation equipment, filters, door seals, and entrances and exits of buildings.

For chemical agents or degradation products the typical sample collection kit will contain equipment suitable for the following types of sample: neat chemical agent (solid or liquid), wastewater, air, concrete, rubber, paint, swabs/wipes, soil, and vegetation and debris. A list of equipment in a typical sampling kit is shown in Table 1.

The use of specialist equipment, for example power augers, sampling drills, crushers and mills, is not envisaged for the types of investigation and inspection carried out by the OPCW. However, it has been decided that for the sampling of intact munitions a safe system for automatically drilling and sampling the contents is required and a specification for such a piece of equipment is to be produced, but as yet the OPCW has not acquired such a system.

2.4 Sample Management

The CWC specifies that during the course of inspection activities there may be a requirement to resolve ambiguities by sampling and analysis. The result of this process must stand up to international scrutiny and be legally and scientifically defensible. The sample must therefore be collected and handled in such a way that the data obtained can be used in evidence when proving compliance or noncompliance with the CWC. The elements of a sample management system include unique sample identification, chain-of-custody or auditable procedures throughout the life of the sample, documentation or logging procedures, sample-splitting techniques, transportation, preservation, antitampering and storage. These are dealt with next in a logical sequence.

When a sample is collected it is given a unique identification number. This may be used to indicate not only a rolling number, but also a site code, the sampler’s identity, and the sample matrix. A suffix may be added later to indicate other events.

When a sample is collected a sample log-sheet should be completed detailing all necessary information relating to that specific sample, such as time, date, position (site related or using global positioning system (GPS) data), sample identification number, why the sample was taken, detector responses, in fact everything pertinent to that sample. It may also be prudent, if safe to do so, to photograph the sample location and the sampling process. This document should then accompany the sample to the reception area, as all information about the sample is important in the analytical processes which follow.

The chain-of-custody procedure begins immediately a sample is taken and is maintained throughout the life of the sample. The process should allow the re-creation of the position or state of the sample at any time during the handling of the sample from cradle to grave. When a sample is taken, unique tamper-proof seals should be applied to the sample container. The number of the seal should be entered on the sample log-sheet and a “traveler” form prepared, which will accompany the sample.

A traveler form is a document on which all sample transfers are recorded. When the sample is passed between individuals this movement is recorded by the signature of both the donor and the receiver, and this is repeated whenever a transfer is made. When movement of the sample is to an off-site location the transport container will be packed and uniquely sealed in the presence of the accompanying inspector, who will take it into his/her custody and sign the traveler form. When the sample reaches its destination the receiver will sign it into their custody only on opening the transit container and confirming the integrity of the sample. Whenever a sample is subdivided, the subdivision is allocated a new number, usually an extension of the parent number with an appropriate suffix. This subsample will then be treated in exactly the same manner as the original and a new traveler form will be initiated.

Whenever a sample is taken for subsequent analysis, whether on- or off-site, it will be subdivided or split. The number of subdivisions will depend on the eventual disposition of the sample; for example, an initial distribution between the IT and the inspected State Party may be followed by an eight-fold split for distribution off-site. Each subsample will be put into a clean sample container and labelled and sealed with a security seal. Blank samples will be treated in exactly the same way.

2.5 Sample Splitting

The techniques used for splitting samples will vary according to sample type. The process for splitting liquid

PVC, poly(vinyl chloride); PTFE, poly(tetrafluoroethylene).

Samples or swab/wipe samples is much simpler than that for solid samples. For liquids, a pipette is used to place equal volumes of well-mixed sample into eight separate containers. For swab/wipe samples, a solvent is first used to extract any soluble nonpolar analytes from the material. This procedure is carried out at least twice, then the resultant solutions are mixed and divided equally between eight containers. The swab/wipe is allowed to dry, so any remaining solvent evaporates, then it is extracted twice with water to remove any
polar analytes and the resultant solutions are mixed and divided equally as described for liquid samples. If aqueous samples are taken and then subsampled for analysis off-site a preservative is added to prevent degradation due to bacterial action. The addition of approximately 0.1% methylene chloride to the main sample followed by thorough mixing will ensure stabilization until analysis can be carried out. After standing for a few minutes the sample can be subdivided.

When splitting soil or bulk solid samples the process has to be more thorough to ensure homogeneity and give fully representative samples for analysis. The rationale behind subsampling or splitting for subsequent analysis is normally to provide one sample that is representative of the whole, but in this case it is to provide eight similar samples. The method chosen by the OPCW for carrying out this process is cone-and-quartering, the only requirement of the method being that the sample is dry and free-flowing. Cone-and-quartering is an internationally accepted procedure for subsampling nonhomogeneous soil and bulk samples. Because of the possibly toxic nature of the samples the procedure is carried out within the confines of a fumehood or an impermeable glovebag, or alternatively it may be carried out in the field wearing suitable protective clothing and a respirator. After sieving (1.7 mm mesh) and thorough mixing about 400 g of the sample is placed on a clean nonabsorbent surface (25 cm square board covered with aluminum foil) in a cone-shaped pile. The pile is then flattened with a second board until it is about a quarter of its original height and divided into four roughly equal parts by making right-angled cuts through the centre of the pile with a spatula. One pair of opposite corners is then transferred to another board and the quartering process is repeated for the two re-formed piles. The pairs of opposite corners from the two boards are then transferred to two more boards and the process is repeated for all four boards. After quartering, the eight pairs of opposite corners can be placed in clean sample jars using the spatula. The aluminum foil is removed from the boards for decontamination and disposal, and new foil is used for each additional sample. Other methods available for splitting samples include “riffling” or the use of rotary sample dividers, but the method described is convenient in that it uses few items of kit, enables easy decontamination and is widely applicable.

2.6 Sample Transportation

During the course of inspections samples may be taken which will be neat chemicals or highly contaminated environmental samples. If these samples are to be analyzed off-site then they must be transported in such a way as to preserve the sample integrity and also ensure the safety of the carrier. The integrity of the sample should be preserved by ensuring that measures are taken to eliminate or minimize degradation. Factors that can influence the stability of the sample include air, water, direct sunlight and temperature, and therefore exposure to these effects should be kept to a minimum. Generally it is best to pack the samples in packaging which excludes light, moisture and air, undertake analysis as soon as possible after sample collection and only open the sample container when ready to carry out analysis. When samples are transported off-site to the OPCW, or to designated laboratories, transportation time should be minimized and this means they will generally travel by air. The transportation of dangerous goods by commercial aircraft is regulated by the International Civil Aviation Organization (ICAO) and the system is based upon recommendations from the United Nations committee of experts on the transport of dangerous goods. A manual based on the ICAO instructions is produced by the International Air Transport Association (IATA) and this is rigorously followed by the commercial airline industry. Dangerous goods are categorised in hazard classes from 1 to 9, dependent upon their type and hazard. Class 6 covers poisonous and infectious substances. CW-relevant chemicals are therefore covered by hazard class 6.1, with class 6.2 covering infectious substances. Dangerous goods are also classified in three packing groups based on the associated hazards. For chemicals this is based on their toxicity and for CW-related compounds a full descriptor would be hazard class 6.1, packing group 1.

Until recently, the IATA regulations stipulated that the transport of CW-related chemicals by air was strictly forbidden; however this has been addressed by the use of special containers specifically designed for the OPCW by the United Kingdom and the United States of America. These systems meet the criteria laid down by the ICAO for the air transport of CW-related chemicals and have been granted a Certificate of Packaging Performance (packing instruction 623). An IATA special provision (A106) applies to the movement of samples, and this states that the provision may only be used for samples of chemicals taken for analysis in connection with the implementation of the CWC. The UK ToxRea Transport Container allows for the packaging of a total of 800 mg of neat material, or eight vapor adsorption tubes, or 80 g of dilute material, or a proportional mixture, contained in eight separate primary containers. The US Protective Sample Container allows for the packaging of a total of 350 mL of unspecified chemical sample, contained within seven primary containers.

When packing samples for transportation, mixing of different samples within the same secondary container should be avoided, although packing separate aliquots of the same sample is permissible. Once the secondary
containers have been packed into the transport system it should be sealed with a high-security seal, such as a fiber optic seal, and the seal record can then be checked for tampering on arrival at its destination. When samples are moved in this way a member of the IT will be assigned to accompany the container on its journey to the OPCW laboratory. The team member will travel with the container whenever possible, witnessing transfers, loading and unloading, to ensure the chain of custody is not broken.

The IT is responsible for ensuring that all the required documentation is completed whenever samples are shipped off-site. Although the bulk of this documentation will be prepared by the OPCW in advance, the IT should be familiar with, and capable of processing, all the necessary forms. The IT (shipper) will fill out the “Shippers Declaration for Dangerous Goods”. This form contains all necessary information and must be filled out correctly, in English, and contain no alterations, unless signed by the shipper. The form must contain the proper name of the goods as listed in the IATA regulations. For CW-related materials this is “chemical sample, toxic, liquid or solid”, the hazard class 6.1 and the packing instruction 623. An air waybill for dangerous goods is also required.

Once samples have been signed into the secure storage at the OPCW facility any access will be audited, to ensure the chain of custody is not broken, until the samples are despatched to designated laboratories for analysis.

2.7 Sample Collection Techniques

The sample collection process begins in earnest upon arrival at the inspection site. In most cases time will be at a premium, and therefore strict organization of all stages of the process is essential. The sampling and detection equipment should be unpacked and organized as soon as possible after arrival on-site. If a laboratory is also to be set up, then two separate but easily accessible areas should be established. This will allow for good communication and also prevent any contamination control problems. The first stage of any inspection is to carry out a “windshield” tour of the facility, and depending on the size of the site this may either be on foot or in vehicles. This familiarizes the inspectors with the site layout, gives a reasonable idea of sampling locations and facilitates the final planning of the inspection. This stage in the inspection process, before any equipment is exposed to contaminated areas, provides the first opportunity for collection of blanks. Because actual samples have yet to be decided upon it will be necessary to collect a variety of blanks, concentrating on air, water and soil. The selection of which blanks to take and which areas to sample will be at the discretion of the IT, who can only decide after careful consideration of the characteristics of the site. The use of detectors to show the absence of CW contamination will aid in the collection of these samples.

After the initial formalities of site briefings and negotiation and planning procedures have been dealt with, the inspection activities will begin. Depending upon the number of inspectors present on the mission, one or more subteams will carry out a thorough investigation of the site. The site safety assessment undertaken in the initial stages of planning will have determined the hazards present on-site and will dictate the level of protective clothing to be worn during any stage of the inspection process. The following description of the sampling process assumes that the IT will be taking the samples. If, on-site personnel carry out sample collection most of the procedures will still apply, as the IT will need to witness the act of sampling and the on-site personnel will be using equipment belonging to the IT. During the course of the inspection the sample collection teams will be subjected to the most arduous and dangerous aspects of the verification procedure, therefore they should be fully trained and appreciate all aspects of the chemical and physical hazards to which they could be exposed. They must be able to act appropriately in emergency situations brought about by physical injury or exposure to chemicals and therefore must be trained in all aspects of basic first aid.

2.8 Sample Collection Team

To carry out the process of sample collection, the size of a team should necessarily be a minimum of three persons. This is the required number to ensure safety and sample integrity. Before starting any sampling operation contamination control line (CCL) must be established in an area known to be free of contamination and preferably upwind of the sampling site. It is normally best to indicate this line by means of tape, and a rigorous regime of controlled entry and exit to the sample collection site should be applied. The kit assembled at the CCL will include decontamination facilities, sampling kit, detection equipment and on-site transport containers. The individual team members are defined in terms of their potential for contamination, and the team is made up of a “hot”, a “warm” and a “cold” person, ranked in order of the possibility of contact with contamination. In larger teams there may be more than one cold person. The duties of the hot person include surveying the suspected contaminated area with detectors to identify “hot spots” and safe entry/exit routes, selection of equipment and sample collection. The warm person acts as an assistant to the hot person by retrieving tools and equipment as requested, if necessary holding the sample container during sampling, and decontaminating the outside of the container before dropping it into a bag held by the cold person. The warm person also acts as a safety link between the CCL and the sampling point, transmits information to the cold person to record on the sample log-sheet and
may also photograph the sampling area if it is inaccessible to the cold members of the team. The cold person controls the sample collection process, and their duties include recording all relevant information as each sample is taken, photographing the area if feasible, passing sampling equipment to the warm person when requested, collecting, labelling and packing decontaminated sample bottles and bags, and checking personnel across the CCL after personal decontamination has taken place.

### 2.9 Sample Types

The number of samples taken may be strictly limited by the analysis time available. Some form of prioritization will therefore need to be addressed, so that the best samples are obtained for analysis. The type of inspection and the specific site concerns will always determine the sort of sample available. For instance, an “alleged use” investigation will provide different sampling opportunities compared with investigation of an industrial site. In general terms, the following decreasing order of priority should be observed: category one samples, then category two samples, and finally category three samples. Category one samples are likely to contain neat chemicals, and include munitions contents, residues or fragments from munitions, bulk storage containers, chemical reactors and process lines. Category two samples include environmental samples, such as soil or water taken from the point of a munitions impact; contaminated paints, plastics or rubber; swabs from munitions or chemical plant; air samples from enclosed areas; and equipment or clothing from affected personnel. Finally, category three samples include body fluids such as blood or urine, vegetation and dead animals or insects.

The sampling kit, as described in Table 1, provides an adequate selection of equipment to deal with any sample collection scenario. The ancillary equipment, such as detectors, tools and general inspection equipment, which will accompany all ITs is not listed. Collection methods or ROPs for the various types of sample that will be taken for CWC verification are similar to those described in the field of industrial and environmental sampling. ROPs for air, solid and liquid samples are also listed in AEP-10 and in the “Blue Book”.

These publications describe the step-by-step process and list the equipment necessary to obtain each type of sample. General guidelines for the collection of various types of sample follow, and in all cases, because of the hazardous nature of the different types of sample, it is essential that the safe operating procedures listed previously are followed. It is also necessary to remember that sufficient material should be collected to allow for subsequent splitting of the sample.

#### 2.9.1 Bulk Samples

Bulk samples from munitions, storage tanks, drums, reactors and process or filling lines are, in essence, neat chemicals or concentrated solutions and therefore only a relatively small amount of material is required for analysis. For solid material, a spatula should be used to remove approximately 10–20 g of material and place it in a glass wide-neck bottle with a Teflon®-lined cap. For liquid bulk samples in containers which are easily accessible several techniques are available and the sampler will need to decide upon the most appropriate method. Collection can be carried out using the Vacutainer® system, a syringe, a pipette or by simply utilizing container facilities such as fitted taps. The sampling kit does not allow for samples to be taken from intact munitions, except in those cases where munitions experts are on-hand to give advice and if possible remove filling caps when the munition has been declared safe. Samples from reactors and process or filling lines should only be taken when the specialist advice of a chemical engineer or plant operative is available. The main concern with chemical plants is that the contents may be under increased or decreased pressure and may also be at an elevated temperature. In this case it is sensible to allow an experienced operative to take the sample while the process is witnessed by the sampling team. The amount of sample required is again small and 10–20 mL should suffice. The exception is in those cases where the sample is known to be a dilute solution of chemicals in a solvent, when a larger amount (approximately 400 mL) should be taken. Because of the extreme hazard associated with neat chemicals it is essential that the most rigorous safety regime is adopted for this sample type.

#### 2.9.2 Air Samples

Air or vapour samples are taken for several reasons during inspection activities and may be used for verification or safety. In a safety role, and provided an on-site laboratory is available, air monitoring can be carried out to establish background levels of chemical contamination, thus aiding the IT in the operation of its mission by enabling appropriate protective measures to be chosen. In a verification role air sampling is carried out if it is felt that other sample types are either unobtainable or will give inconclusive results. For example, a complicated sample matrix may give poor analytical results whereas vapour collected from off-gassing gives a clear result. It may also be impossible to collect material samples from a demolished building or munitions bunker, whereas a sample may be taken by inserting a probe into the area and sampling onto the adsorbent tube. Samples may be taken using either a mechanical or a hand pump, and a collection volume of approximately 10 L should be sufficient. The tubes supplied with the sampling kit include both Tenax® and

Carbosieve® as sampling media. These tubes should be capable of dealing with a wide range of chemicals although exceptions include those with high boiling points, such as ethyl S-2-diisopropylaminoethyl methylphosphonothiolate (VX) and bis(2-chloroethylthioethyl)ether (T), which are difficult to thermally desorb from the tubes but may be eluted with solvents. Table 2 lists abbreviations, common names and chemical names of classical chemical agents.

2.9.3 Soil Samples

The collection of solid/soil samples will be associated mainly with the following types of inspection: alleged use, storage facilities and industrial sites. The retrospective identification of chemicals used on-site, or recently deployed in a military sense, is possible by analysis for intact CWC-related chemicals or more likely their degradation products. It may be possible to identify areas of interest for sampling in several ways. Color differences from the surroundings may indicate areas of contamination, detector responses will be obtained from highly contaminated ground, and areas of disturbance such as bomb craters or dumping grounds will be visible. Approximately 400 g of sample will be required for splitting and subsequent analysis; an area approximately 10 cm × 10 cm should be selected and soil removed to a depth of 1–2 cm. A spatula or stainless steel scoop is used and the sample is placed in a 400 mL wide-necked bottle with a Teflon® cap, or in a Mylar® bag which is then sealed with tape.

2.9.4 Water Samples

Aqueous liquid samples will be taken for similar scenarios to soil samples. In this case, however, detectors will be of limited use and sampling points will need to be identified from pointers on the ground and surroundings. Sampling opportunities to look for include pools of water near or in bomb craters; runoff water collected in depressions; and in industrial facilities, wastewater containers, drains and treatment plants. The selection of sampling kit will vary from sample to sample and common sense on the part...
of the sampler will be needed. There should, however, always be a way of obtaining a sample by using a syringe, pipette, Vacutainer® or dipper, and in all cases the amount collected should be approximately 400 mL to allow for subdivision.

2.9.5 Swab Samples

The use of swabs or wipes to collect samples is a technique which allows samples to be taken from surfaces previously wetted or exposed to chemicals. In situations where munitions or chemical plants are found to be leaking this may be the only available technique for acquiring samples. Other collection situations include contaminated ventilation equipment, shelving or walls inside storage bunkers, loading trolleys, vehicles and other equipment exposed to chemicals. Swabs can be made of either pre-cleaned cloth or cotton wool. The technique is to hold the material with a pair of forceps, moisten the swab with a solvent (normally isopropanol), and then swab an area of approximately 15 cm × 15 cm. The swab is then placed into a clean screw-top bottle and subsequently extracted with further solvent before analysis.

2.9.6 Material Samples

Other samples may be taken if the sampling team considers it necessary. In some scenarios sampling opportunities will be few and the best sample may not necessarily be of a conventional type. Some examples include material gaskets or rubber flanges from chemical plants, door seals from storage bunkers, filter units from ventilation equipment, electrical cabling, vehicle tyres, plastic storage containers and protective clothing. These items are all made from plastic or rubber materials and as such they are extremely good sampling media for organic chemicals. Samples can be taken using any of the cutting implements in the sampling kit and then they should either be placed in glass wide-necked bottles or double-wrapped in Mylar® bags.

3 SCREENING

In this context, screening is the use of specialized equipment to carry out a survey of a site to determine areas of a hazardous nature to the sampling team. It also aims to provide an indication of the presence of chemical contamination and pinpoint the site of maximum contamination. This is true for many situations, but for trace levels of contamination, for instance in alleged use investigations, the use of detectors will not always be feasible. The use of detectors in the inspection of CW-related sites will assist the IT in several important ways.

Three areas where screening with chemical detectors can help to expedite the mission are safety monitoring, contamination mapping and sample selection.

4 DETECTION

4.1 Use of Detectors

A number of systems can be used for the real-time monitoring of the hazards from volatile chemical materials present on-site. Other techniques that can determine the hazards from nonvolatile material are not real-time, but could be employed in an on-site laboratory to provide effective monitoring, allowing contaminated areas to be identified. Many of the field detectors in current use by armed forces actively sample air but are only set up to detect a limited number of volatile chemicals of CWC concern. The low-volatility agents are detected by modifications of these detectors or by different tests. A selection of current screening technologies is briefly discussed and reviewed in terms of their use on-site for screening for chemicals identified as presenting a hazard. A more thorough treatment is presented in the article Detection and Screening of Chemicals Related to the Chemical Weapons Convention in this publication.

4.2 Ion Mobility Spectrometry

Ion mobility spectrometry (IMS) is employed in handheld, field-deployable instruments which are very useful in the real-time determination of hazards presented by certain CWC-related chemicals. It is recommended that these instruments are used in the field to aid identification of suitable sampling sites, as a safety system in the CCL, and in an air monitoring role. Two instruments that work on this principle are employed by the OPCW: the chemical agent monitor (CAM, Graseby Ionics, UK); and the German rapid alarm and identification detector (RAID-1, Bruker-Saxonia Analytik, Germany). In its normal set-up a CAM will detect H (sulfur mustard) and the nerve agents GA, GB, GD and VX, but it is not set up to detect the whole spectrum of chemicals listed in the CWC schedules. It is possible that the programming could be changed so that a CAM could detect volatile agents of concern to a particular site, but this is not a modification currently within the skills of an inspector. The RAID-1 unit has the capability of detecting both sulfur and nitrogen mustards (H, HN1, HN2, and HN3), lewisite, the nerve agents GA, GB, GD, GF and VX, and also the blood agents AC, CK and CG. It has a more sophisticated display than a CAM in that it will also display the identity of the chemical detected and its agent group, and give an audible alarm. Both detectors display
a measured concentration range and can be deployed in a stationary or mobile role. They have similar sensitivities, i.e. 0.1 mg m\(^{-3}\) for the blister agents (H, HN1, HN2, HN3, and LI) and VX and 0.03 mg m\(^{-3}\) for the G-agents.

### 4.3 Flame Photometric Detection

Flame photometric detection (FPD) technology is used in the hand-held AP2C field detection system developed by the French (PROENGIN, France). The detector can be used in the field in a similar role to the IMS systems. It is set up to detect volatile chemicals in both the sulfur and phosphorus modes. This limits the use of this system on-site to the detection of volatile sulfur- or phosphorus-containing CW-related compounds. The system differentiates between the two families of chemicals but does not have the selectivity demonstrated by IMS detectors. The sensitivity of the AP2C detector is 0.01 mg m\(^{-3}\) for most phosphorus compounds and 0.6 mg m\(^{-3}\) for sulfur mustard (H).

### 4.4 Detector Papers

Military detector papers are used on the battlefield to determine the presence of liquid agents. They employ the principle of microencapsulated dye solubility to give rise to color development at the paper's surface. These papers are of limited value for on-site use except where ground or surface contamination is suspected. They can be used in a site screening role by taping the paper to a roller fixed to a pole, which is then rolled over suspected ground contamination. There are two types of paper available: single color, which responds to all CW-related chemicals; and three color, which discriminates between mustard (red), G-agents (amber) and VX (green).

### 4.5 Detector Tubes

Detection tubes containing reagents immobilized on a solid adsorbent are used for sampling gases and vapors. Two systems are employed by the OPCW inspectors: the Czech military chemical detection kit ORI-217 (ORITEST, Prague), and the commercial Auergesellschaft/Mine Safety Appliances Gas Tester IIH kit (AUERGESELLSCHAFT, Germany). The detector tubes are either chemical in which the analyte reacts with a specific reagent giving a characteristic color change, or enzyme-based where the analyte of interest inhibits the enzyme. The ORI-217 kit specifically targets a range of classical CW-related compounds and contains four types of tube for the detection of the nerve agents GA, GB, GD, GF and VX, the choking and blood agents CG, DP, CK and AC, and the blister agents H and LI. The AUER/MSA kit is a general purpose gas-testing kit which utilizes a wide range of tubes mainly concentrating on the safety monitoring of industrial gases and vapors, for example chlorine, AC, CG, hydrogen sulfide and sulfur dioxide.

### 4.6 On-site Analysis Equipment

In addition to the detector systems mentioned previously, the use of on-site analysis equipment which can be used to rapidly screen samples in the field or in small portable laboratories will aid the verification process. For the present, OPCW inspectors have to rely on the use of detection equipment, sampling and on-site analysis to map the contamination of the site. In the future, especially when large areas are involved, other quick on-site analytical screening methods could be utilized. Two such items of equipment, one an off-the-shelf commercial product, the second a product in development, are briefly described below.

#### 4.6.1 Element Specific Detection

Atomic fluorescence total arsenic determination is a quick screening technique for different arsenic compounds believed to be present on-site. It may, in certain investigations, be important to have an indication of the total levels of arsenic present in organic extracts and aqueous extracts of soil and other matrices. This can easily be achieved using an atomic fluorescence detector (e.g. The Excalibur Plus system, P.S. Analytical, UK). The sample is reacted with acidic borohydride to produce SA gas, which passes on through a flame and is detected by the atomic fluorescence detector. This is a very simple system which could be set up in an on-site laboratory to give a fast screening capability to aid in the pinpointing of contamination on site.

#### 4.6.2 Specific Degradation Product Detection

An emerging technology for site screening is the chemiluminescence (CL) screen for thiodiglycol,\(^{[6]}\) the major breakdown product of H. Porton Down has developed a fast, sensitive and specific screen for thiodiglycol in soil. The thiodiglycol in the sample is oxidized with sodium hypochlorite to produce a high-energy species. The energy from this species is transferred to a rhodamine B sensitizer. The CL produced from this reaction is detected and is directly related to the quantity of thiodiglycol present in the extract. The thiodiglycol is extracted by simply shaking with a small quantity of methanol. An aliquot of this extract is injected into the flow injection system and the result is determined within a minute. This system is applicable to field operations and could easily be set up in a mobile laboratory. The presence of mustard in the sample is also easily determined.
by carrying out a simple hydrolysis step and re-measuring the thiodiglycol. Mustard, although a World War I chemical agent, is still one of the major CWC concerns and a quick and reliable screen will aid the CW inspectors in inspections of alleged use, production and storage.

1 INTRODUCTION

The amount of chemical knowledge in the field of clinical chemistry is enormous, is growing rapidly and the task of restricting information presented to an encyclopedia-sized document is difficult. Nearly every topic included in undergraduate quantitative analysis and instrumental analytical chemistry courses is used in clinical chemistry laboratories as well as many methods from the fields of biochemistry and medicine.

An analytical chemistry mission statement for the clinical chemistry portion of clinical laboratories could be stated as: the application of analytical chemistry principles, methods and instruments to measurements of solids, fluids, tissues, cellular components and other biological materials for the measurement of more than 500 analytes to produce data to help in the diagnosis and prognosis of human diseases.

Organization of this section and the entire encyclopedia is a daunting task. There are more than 600 articles in total and more than 30 articles in the Clinical Chemistry section that will focus on the more common topics. It is an organizational dilemma as to what to include in the clinical chemistry section.

One way to view the field of clinical chemistry is to examine the “organ based medical curriculum” as is often used to arrange the medical school courses. This would allow us to organize clinical chemistry to include those laboratory tests that seek information about organ systems. The organ systems may include the brain and peripheral nervous system, lungs, kidneys, liver, muscles, bones, bone marrow and all the endocrine and exocrine gland systems. One could also organize the section by the classes of analytes frequently encountered in clinical chemistry and those classes of tests could include illicit and prescription drugs, lipids, electrolytes, blood gases, endocrine hormones, glucose, blood urea nitrogen, creatinine, DNA–RNA, proteins, peptides, enzyme activities, enzyme mass and therapeutic drug monitoring. Still another way to view the field of clinical chemistry would be to examine the laboratory tests of the various organ systems when and after those systems are challenged. For example, one would study the pancreas by examination of glucose concentration change after the subject ingests a large dose of glucose (glucose tolerance test). Kidney, nitrogen metabolism, endocrine function and liver function tests also may use additions of substrates or metabolites to glean information about the function of the organ system of interest. Heart, lungs and kidney function, however, are usually conducted by analysis of naturally occurring metabolites without an exogenous challenge. For organization of this section, a sampling of all three of the above approaches was used.

A goal of this section is to rely upon the other sections for most of the analytical chemistry principles, procedures, descriptions of the instruments and even borrow the exact methods for application in clinical chemistry cases. For example most of the information in DNA–RNA analyses, on nucleic acid sequencing, on the genome project and on genetic screening are in articles in those sections of this encyclopedia. Most of the information about gel electrophoresis, capillary electrophoresis (CE), point-of-care testing, field flow fractionation, protein and peptide analysis are likewise in those sections that describe the techniques. In a similar manner, ion-selective electrodes, voltametry, amperometry, kinetic measurements, ultraviolet/visible (UV/VIS) and infrared (IR) spectrophotometry, and pH measurements are found in other sections of this encyclopedia. Previously IR was used for kidney and gall stone analysis in clinical chemistry laboratories. Especially interesting are the new proposals concerning the use of near-IR for noninvasive reflective or absorption analysis for glucose monitoring and other metabolite analysis without removal of a sample from the patient. An article on this subject is found in this encyclopedia.

Until recently UV/VIS absorption spectrophotometry was the most common read-out for the analyses performed. With the increases in automation and the huge multichannel analytical instruments, a larger number of measurements are now made with ion-selective electrodes. Fluorescence, phosphorescence, chemiluminescence and the use of radioactive tracers have increased significantly in the past 15 years in support of the use of immunological methods of analysis. Molecules such as antibodies, antigens, proteins and/or protein-like reagents are used in competitive binding and/or isotope dilution-type analyses. Automated analytical instruments have blended computers into the instruments for both process
control and for the calculation of results such that computers are an integral part of the measurement package. Many such instruments use kinetic methods, either end-point or rate measurement techniques, to determine enzyme activities important for patient care.

Chromatography has become an indispensable technique in clinical chemistry laboratories. Thin-layer chromatography was widely used for determining the presence of drugs of abuse, for concentrations of therapeutic drugs and for lipid analyses until newer instrumentation became available. The use of high-performance liquid chromatography (HPLC), gas–liquid chromatography (GLC), CE, supercritical fluid chromatography, size exclusion chromatography and other separation instruments are directly interfaced to low resolution mass spectrometers. These types of instruments have become more common in clinical chemistry laboratories. These instruments are used both for forensic testing and for toxicological identifications in clinical laboratories. Modification of these instruments using thermospray, electrospray volatilization and matrix-assisted laser desorption/ionization (MALDI) has been achieved for proteins, peptides and hormones in the clinical chemistry laboratory.

Emission flame spectrophotometry for sodium, potassium and lithium and atomic absorption spectrometry (AAS) for calcium and magnesium in serum and urine were the standard techniques used for years. Flame atomic absorption for calcium, magnesium and in some cases lithium became the method of choice in the 1960s. More recently, ion-selective electrodes have replaced these techniques in the larger more modern clinical chemistry laboratories. Graphite furnace AAS and inductively coupled plasma (ICP) emission and mass spectrometry (MS) have become more routine in some clinical chemistry laboratories. These instruments are used for forensic testing and for toxicological identifications in clinical laboratories. Modification of these instruments using thermospray, electrospray volatilization and matrix-assisted laser desorption/ionization (MALDI) has been achieved for proteins, peptides and hormones in the clinical chemistry laboratory.

When we examine the subjects in the fundamental and applied reviews of Analytical Chemistry, published in alternate years, we will notice that nearly all the subject headings in these two reviews are used daily in clinical chemistry laboratories. Hence, the subject matter knowledge required in these types of service laboratories is indeed encyclopedic in breadth and in depth!

2 PAST

If we look historically at this field, we will notice that biochemists began working in hospital laboratories in the USA at about the turn of the century – mostly in large cities like Boston, New York and in other eastern cities where Ivy League colleges are located. Shortly thereafter, many of these biochemists sought more academic freedom, started independent departments, created new journals and began working on nonhuman biological problems. If one looks at the first issue of the Biochemical Journal published in 1906, one notices that in northern Europe and in the UK there were many studies on measuring components of blood and urine. In the USA a few of the original clinical biochemists remained closely connected to medical schools. Folin, often called the first clinical biochemist, and Wu of Harvard, Peters at Yale, Van Slyke of New York and Somogyi in St Louis became the founders of the new field of quantitative clinical chemistry. In the mid-1940s hospital biochemists in the New York City area began to organize a professional organization that would eventually become the American Association of Clinical Chemistry (AACC). In the late 1940s, led by Max Friedman, the journal Clinical Chemistry was started. In the early 1960s, Analytical Chemistry began to publish articles by academic chemists on kinetic measurement of enzymes, on enzyme electrodes, and on enzymes as analytical reagents. Biochemistry, first published in 1962, had several articles on the use of physicochemical studies on enzymes and proteins in blood and urine. The earlier mathematical focus, on enzyme kinetic studies, borrowed from physical chemistry by Michaelis and Menten and adapted to a graphical presentation by Lineweaver and Burk, became the foundation for a whole field of study by the clinical biochemists. In the mid-1960s analytical chemistry divisions in mostly midwestern universities began to apply the “Measurement Science” component of analytical chemistry to clinical chemistry. These university research laboratories developed the early instruments using enzyme kinetics as the basis for their instrumentation. About this same time in other academic analytical chemistry research laboratories, some automated instruments were being built for the drug industry. Kolthoff, at the University of Minnesota, often considered one of the founders of modern analytical chemistry as a separate division in chemistry departments, noticed that analytical chemistry measurements had much to contribute to the pharmaceutical industry for their drug analysis needs and he promoted this application.

In the late 1950s Technicon of Ardsley, New York took the Auto Analyzer developments of Skeggs to commercial availability. This was the beginning of a flurry of mechanization, automation and instrument building that would soon become much larger than originally thought possible only a few years earlier. Other large companies, Du Pont, Beckman, Kodak, Xerox, Dow, Perkin-Elmer, Hewlett-Packard and others, created instruments and products for the centralized clinical chemistry laboratory. Since the early 1960s enormous growth has continued in the contributions of analytical chemistry to clinical chemistry. The application of absorption spectrophotometry, enzyme
kinetics, statistics, electrochemistry, chromatography, and computers for data collection, for data calculations and reporting of results, along with record keeping, and billing of charges have become subjects of study and contributions by analytical chemists.

It is easily evident that the two major roots for clinical chemistry evolved from the field of biochemistry (for the early biochemistry principles) and then later attracted interest from analytical chemistry (for the development of instrumentation, quantitation, and specific method development). More recently, instrument development has focused on hand-held instruments. “Point-of-care” testing instruments such as glucose meters for diabetics, home test kits and portable pH meters are examples. More sophisticated hand-held instruments such as the I-Stat, which can measure up to nine analytes in 90 s with a single drop of blood, are now widely available. These developments are directed at the decentralization of large clinical laboratories and the moving of testing closer to the patient, which will quicken the turn around time of analytical results for patient care.

3 PRESENT

The main objective for the section on clinical chemistry is to provide a broad overview of the field in the evolving health care industry as we enter the 21st century, and to illustrate how most of the fundamental principles, methods and instruments of analytical chemistry are being applied to this field.

The first objective was to select some of the more common methods of analysis and to ask the authors of these articles to illustrate how these analytical approaches, methods, and techniques are used in typical hospital clinical chemistry laboratories. These articles include automation, biosensors, CE, HPLC, gas chromatography/mass spectrometry (GC/MS), planar chromatography, electrochemistry, electrophoresis, IR spectrophotometry, enzymology, UV/VIS spectrophotometry, and DNA analysis in the areas of molecular diagnostics and molecular pathology. In addition, drug testing for clinical toxicology and forensic toxicology cases and the statistical quality control of laboratory results were included for the instrumental analysis areas of this section. Next, a few of the more common human diseases were selected. Topics related to analysis in endocrinology, hematology, heart disease, liver diseases, atherosclerosis, genetic diseases, and diabetes and then authors were asked to describe how measurements from the clinical chemistry laboratory contributed to the information that physicians use in managing the health care of patients with these medical conditions. Finally, authors were selected for some of the more common analytes such as lipids, nucleic acids, drugs, glucose, cardiac markers, electrolytes, blood pH, enzymes, proteins, peptides, and hormones and it was suggested that they illustrate the analytical chemistry used for these analytes and how the laboratory information contributes to patient care. Together, these three approaches provide a representative coverage of the vast range of analytical chemistry techniques used in the very large spectrum of different diseases found in the typical hospital clinical chemistry laboratory.

The large commercial clinical laboratories provide yet another use of instrumental analytical chemistry measurements in clinical chemistry. These companies use large, complex computer-controlled analytical instruments that produce thousands of results per hour at a cost of pennies per result. Another role for commercial clinical chemistry laboratories is to perform extremely difficult and expensive laboratory tests that are requested infrequently of routine hospital laboratories. These esoteric analyses support the management of more complex disease patients.

There are some excellent up-to-date textbooks that provide significant analytical chemistry fundamentals as well as human physiological chemistry principles. Two examples of these textbooks are the Tietz Textbook of Clinical Chemistry, edited by Burtis and Ashworth, and published by Saunders, and Harrison’s Principals of Internal Medicine, edited by Fauci and published by McGraw-Hill. These textbooks are used by the physicians as resources for the interpretation of laboratory results generated by the clinical laboratory. Details of the Fundamentals of analytical chemistry and principles of the instrumental analysis methods are found in other textbooks mentioned elsewhere in this encyclopedia.

Another excellent source of up-to-date books, chapters and published articles on clinical chemistry is published in alternate years by Analytical Chemistry in its “Application Reviews”. There are sections on clinical chemistry, on drug analysis, on forensic analyses and on the analysis of proteins and peptides. All these areas do have applications in clinical chemistry. The Fundamental Reviews of Analytical Chemistry, again published in alternate years, provide the principles and physicochemical foundations for the instrumentation discussed in the “Application Reviews”.

There are a couple of areas of analytical chemistry often taken for granted or not considered when tests are requested. These two areas are sampling errors and the analytical process. One can keep in mind the general outline of the generalized “analytical process” listed below. Each time a physician requests a test, the entire list of tasks is utilized. In many situations, the different individuals performing the jobs are unaware of the importance of the whole list and are unaware of how their efforts fit into the overall procedure of producing a
laboratory result. An often-used list of tasks included in the "analytical process" is as follows:

1. blood collection (sampling)
2. sample transport
3. validation of sample
4. sample preparation steps
5. choice of methods to be used
6. use of standards, calibrators and controls
7. initial collection of analytical raw data
8. preliminary calculation of analytical results
9. re-calculation considering blank effects, interferences, matrix effects, enhancement or quenching of analytical signal
10. use of statistics to evaluate the preliminary results
11. method comparison of result to different physico-chemical analysis of same material when questions arise
12. consideration of other information for analytical result
13. report final result using statistics including accuracy and precision
14. conversion of analytical result into clinical meaning or interpretation
15. re-evaluation of all the steps in the "analytical process"
16. reporting the final result.

Next a few words about the potential for sampling error. In the clinical chemistry laboratory the most common sample analyzed is human blood. Let us for a moment examine the magnitude of the potential sampling error in that process. In general blood will account for 5–8% of the body weight of an individual. A 75-kg man has between 3.75 kg and 6.0 kg of blood. Let us use 5 kg or 5 L of blood as an example. Venous sampling of blood will usually remove 5 mL of blood. For a manual cell counting through a microscope or for a modern clinical instrument 10 µL of blood or serum (liquid portion of blood with cells removed) will be taken for analysis. For a whole blood cell count, a small drop of blood will be spread thinly on a glass slide and a total of 100 different types of blood cells are counted. From the percentages of each of the cell types of these 100 counted cells, the results will be multiplied to give the millions of cells present in 1 mL of blood. Just think of the potential sampling errors! Yet, this sampling procedure has worked well for almost 100 years.

A similar situation occurs when a clinical chemistry instrument picks up a 10-µL sample, does the analysis for one or more analytes and calculates the number of moles per liter (older common units were milligrams per 100 mL) and then reports these results to the physicians that made the request. Once again, one must realize that the serum is about 50% of whole blood, that perhaps 3–5 mL of blood were drawn from the patient, and the instrument for the analysis used 10 µL. One would expect the sampling error to be large but it has never been a significant problem for clinical chemists.

In summary, all the principles of analytical chemistry are critically important for the accurate and precise results obtained in the clinical chemistry laboratory. In addition, nearly every method and/or technique studied in analytical chemistry is used in hospital clinical laboratories. Hence, by this measure as well as by the financial size, this is a very large business area with plenty of technical challenges for all the analytical and/or clinical chemists that choose to contribute to this field.

4 FUTURE

In the next few years as the human genome sequencing project nears completion, most supporters of this project believe it will have major effects on what we now know about the human disease processes. Many believe that it will be possible for tightly regulated genetic diseases, along with laboratory results, to predict if an individual will acquire that specific disease. In addition, many believe that once all the DNA sequences are known, researchers will find that there is genetic susceptibility to environment challenges. These challenges also sometimes cause disease. It is hoped that the DNA sequences, measured in the clinical laboratory, will be useful in these medical situations. The tentative names for these projected fields of clinical chemistry are molecular diagnostics and/or molecular pathology.

Another area that is expected to become important is the detection of a single nucleic acid substitution in messenger RNA (mRNA). The demands for accuracy in the laboratory for such nucleotide polymorphism testing are unbelievably high. Consider the situation whereby a single nucleic acid substitution occurs in the mRNA, causing a single amino acid substitution in a critical protein or enzyme. Usually more than 99% of the sequences from one individual to another are identical. Therefore, a single nucleic acid substitution must be detected in hundreds of thousands of different mRNA sequences. In addition, the concentration of the essential mRNA is only one-millimoth of that of other molecules in that sample. MALDI/time-of-flight MS has become the instrument of choice to obtain the necessary accuracy for these types of analyses. Much greater instrumental capabilities will be needed in the future because, at the current time, as the size of the mRNA increases the resolution decreases. Today sequences greater than 50 start to become difficult and inaccurate.

To date, there have been more problems in genetic analyses using DNA–RNA methodologies than expected.
In the case of cystic fibrosis, it was originally thought that the disease involved a single mutation on a single gene. Today, we know there are multiple mutations on multiple genes that relate to the variation and the severity of the disease. It has been estimated that 99% of the DNA is unchanged from individuals and that we only know the functions for about 5% of the DNA found in our bodies. In the case of mRNA, the mRNA may not be translated into a protein, so even if a mutation is accurately found it may not always produce the protein or the enzyme. More knowledge about the mechanisms, kinetics and control of the translation processes from mRNA to protein synthesis will be necessary even if the laboratory analysis is deemed accurate.

One cannot overemphasize the major ramifications that will occur to the medical profession, to the clinical laboratory, to the law profession, to the governmental finances of health care, to the ethics of our society and to individuals when the genetic predisposition to disease tests become accurate and widely used. There will be major perturbations throughout our society when these laboratory tests become available. Already, in the case of cystic fibrosis, in multiple sclerosis, and in other disease conditions, new laboratory tests and diagnostic imaging instrumentation, such as magnetic resonance imaging, are redefining the clinical symptoms that previously were the basis of diagnosis of these diseases. These new tests may cause greater uncertainty for physicians as they manage their patients with complex diseases.

We can conclude that the amount of progress in the field of clinical chemistry in the past 50 years is remarkable. We know that the rate of knowledge and capabilities of instruments in this field continues to expand at a logarithmic rate. We can expect many exciting contributions from the application of analytical chemistry to clinical chemistry in the health care field. We all will benefit as a result.

Atomic Spectrometry in Clinical Chemistry

Patrick J. Parsons
New York State Department of Health, Albany and The University at Albany, Albany, USA

Atomic absorption spectrometry (AAS) and atomic emission spectrometry (AES) are two closely related instrumental techniques that have many applications in many different fields. In clinical chemistry, these techniques are well established for the quantitative measurement of essential and nonessential elements found in body tissues and fluids. For most practical purposes, the elements that are routinely measured with modern commercial instrumentation include almost all of the metallic elements of the s, d and p blocks of the periodic table. The exceptions in the p block include the halogens, the noble gases and the elements C, H, N, O and S. Above atomic number 83 (Bi), only U is measured in absorption. With the emergence of commercial instrumentation for atomic mass spectrometry, e.g. inductively coupled plasma mass spectrometry (ICPMS) clinical chemists have another powerful tool with which to measure multielement composition of biological specimens at ultratrace concentrations, i.e. <10 µg L⁻¹.

With ICPMS, the halogens become detectable, along with B, C, N and Th. The coupling of ICPMS with separation technologies has opened new possibilities in clinical laboratory medicine in the field of speciation.

In some areas of clinical chemistry, older atomic spectroscopy techniques are still considered the reference method for selected clinical applications, e.g. the determination of serum K and serum Na by flame atomic emission spectrometry (FAES). In other areas, flame atomic absorption spectrometry (FAAS) remains the method of choice for serum Mg and serum Cu because of its sensitivity, rapid throughput and the relatively low cost of instrumentation. Electrothermal atomic absorption spectrometry (ETAAS), while more complex than flame atomization methods, is the method of choice for applications such as blood Pb, serum Al and serum Se, where physiological concentrations are too low to be measured in the flame without laborious preconcentration efforts. Robust procedures for quality assurance (QA) and quality control (QC) are now well established within the clinical laboratory and cover the entire spectrum of clinical laboratory activities. These include preanalytical issues, personnel training and education, and also the appropriate use of certified reference materials (CRMs) for method validation purposes. Participation in proficiency testing (PT) programs and external quality assessment schemes (EQAS) for trace elements in biological fluids have also contributed to improved clinical laboratory performance. Despite the advent of ever more sensitive techniques and robust procedures, the quality of results is still only as good as the specimen collected. Contamination can occur at the preanalytical stage of the
analysis and also during the analysis. Selection of the appropriate specimen is critical to obtaining meaningful clinical information about nutritional trace element status or exposure to toxic elements.

1 INTRODUCTION

AAS and AES are two closely related instrumental techniques that are routinely used to determine many of the chemical elements in samples of both environmental and biological origin. Although it is possible to detect almost all naturally occurring elements in biological materials, only a handful of those that can be measured using atomic spectrometry are considered essential for normal healthy growth. Definitions of essentiality vary but the consensus among life scientists appears to be that an element is considered essential if an organism cannot complete its normal life cycle, or achieve normal healthy growth without it, or if the element is part of a molecule that is an essential constituent of normal healthy growth. Thus, the “essential” elements that are of interest in clinical laboratory medicine, and that can be measured directly by atomic spectrometry, are shown in Figure 1 on a simplified version of the periodic table. Many elements are ubiquitous in the environment and are easily detected in human body tissues and fluids. Some are relatively benign, but others are quite toxic even at concentrations considered trace, i.e. below 10 mg L\(^{-1}\) in fluids or <100 mg kg\(^{-1}\) in tissues. Those toxic, nonessential elements that are most frequently encountered in clinical situations are shown in Figure 1 against a shaded background. All elements, including the essential elements, can exhibit toxic effects above a critical concentration threshold. However, a deficiency of essential elements, so that they are present at concentrations below those required for normal health growth, is also associated with adverse health effects. The toxicity of any element will depend on its concentration, duration and route of exposure, as well as the chemical form, i.e. chemical species, of the element. The extent to which some elements have been become clinically, occupationally, or therapeutically significant has been the subject of a review. Some populations may be more at risk, or more sensitive than others, to toxic exposures. For example, patients on hemodialysis, or those on total parenteral nutrition, are at particular risk of exposure to elements such as Al and As. Young children are especially at risk to Pb exposure, because they are more likely to ingest Pb from normal hand-to-mouth activity, and they absorb Pb more efficiently in the gastrointestinal tract compared to adults. Assessment of trace element status is made by analysis of body fluids and tissues, and atomic spectrometry is often the technique of choice because of its sensitivity and selectivity for most of the naturally occurring elements in the periodic table.

In analytical AAS, quantitation is based on the amount of light absorbed at a specific wavelength (\(\lambda\)) by ground state atoms of the analyte in the gas phase. The wavelength selected is a resonance line that is generated by exciting atoms of the element being measured. For many elements, a hollow-cathode lamp (HCL) is an excellent line source. However, for several elements, e.g. Se, P and As, an electrodeless discharge lamp (EDL) is much better. The application of continuum-source AAS instrumentation for the analysis of clinical samples has also been described but the instrumentation is not commercially available and must be assembled in-house.

In analytical AES, quantitation is based on the amount of light emitted by excited atoms as they return to the ground electronic state. A variety of thermal excitation sources are used to achieve atomic emission including flames and inductively coupled plasmas (ICPs). Figure 2 shows the various arrangements for analytical atomic spectrometry in a simplified schematic form. Differences between the technologies include cost and complexity, as well as analytical performance.

The distribution of atoms between the ground state and various excited states is described by Equation (1).

\[
\frac{N_i}{N_0} = g_i e^{-\frac{\Delta E}{kT}}
\]

where \(N_i\) and \(N_0\) are the number of atoms in the \(i\)th excited state and ground state respectively, \(g_i\) and \(g_0\) are the statistical weights of the \(i\)th excited state.
where the terms $h$ and $c$ are the Planck constant $(6.62608 \times 10^{-34} \text{ J s})$ and the speed of light $(2.99792 \times 10^8 \text{ m s}^{-1})$ respectively.

It is clear from the Boltzmann distribution in Equation (1) that, for both AAS and AES, the ratio of excited to unexcited atoms ($N_i/N_0$) of an element will depend on two key variables, $\Delta E$ and $T$. As $\Delta E$ increases, the ratio $N_i/N_0$ decreases. In practical terms, elements such as Zn and Mg, with resonance lines that are well into the ultraviolet (UV) region, i.e. large $\Delta E$ (<350 nm), will have $N_i/N_0$ ratios of the order of $10^{-7}$ to $10^{-11}$ when generated in an air–acetylene flame ($T = 2600 \text{ K}$). In contrast, elements such as Na and K, with resonance lines in the visible region, i.e. small $\Delta E$ (400–750 nm), will have $N_i/N_0$ ratios of the orders $10^{-3}$–$10^{-4}$ in the same flame. As $T$ increases, more atoms are excited and the ratio, $N_i/N_0$, also increases such that for Zn, in an argon ICP ($T = 8000 \text{ K}$), it is of the order of $10^{-3}$. Thus, the choice between AES and AAS will depend on the ratio $N_i/N_0$, which will depend on the element and the wavelength of its resonance line, and on the selection of the atom source, i.e. flame, furnace or ICP. Additionally, the concentration of the analyte will also dictate the selection of technique.

It is obvious that simple flame emission techniques, also called flame photometry, provide adequate sensitivity for Na, K and Li because a significant number of those atoms can be excited, even in an air–propane flame ($T = 2200 \text{ K}$), but Zn and Mg would require an ICP to generate measurable signals in emission. Even in air–acetylene flames, Mg, Zn and Cu are much more sensitive in absorption because the vast majority of the analyte atoms are still in the ground state, where they are available for the absorption transition. Of course there are other factors that may influence the choice between AAS and AES. They include the limitation of AAS (in most commercial instruments) to measuring a single element at a time. While it is possible to determine more than one element simultaneously by AAS, the capability is limited to instruments equipped with multimonomochromator detector systems or, more recently, to instruments equipped with an Echelle dispersion and diode array detector arrangement. Harlby recently evaluated four commercially available multielement line source AAS instruments. Although AES provides the capability of simultaneous multielement analysis, spectral interferences continue to be troublesome, especially in complex biological matrices. Nonetheless, some laboratories do use inductively coupled plasma atomic emission spectrometry (ICPAES) for clinical applications, where information on several elements at microgram per liter concentrations is available within a very short time.

The application of AAS in clinical laboratory medicine is now so well established that, in many situations, it is the preferred analytical technique and, in some instances, it is regarded as the reference method. In recent years, however, ICPMS has emerged as a powerful alternative to AAS and AES. In ICPMS, an ICP is used as an ion source, and is interfaced to a mass spectrometer designed to separate and sort the ions according to their atomic mass (Figure 2). In most typical arrangements, an argon plasma is used with a quadrupole mass analyzer. The sensitivity of ICPMS is generally several orders of magnitude better than either AAS or AES, and this advantage can be exploited for clinical samples by using a higher dilution ratio. Thus, ICPMS can achieve similar method detection limits to AAS because the use of a higher dilution ratio minimizes interferences from the complex biological matrix (see Figure 3). Where several elements must be measured, ICPMS is much faster and its linear dynamic range is greater than either ETAAS or ICPAES.

Typical detection limits for ICPMS range from parts per billion ($\mu\text{g} \text{ L}^{-1}$) to parts per trillion (ng L$^{-1}$), with precision on the order of 2–3%. An important advantage of ICPMS is the opportunity to obtain information on individual isotopes. When used in isotope dilution (ID) analysis mode, the technique can, in experienced hands,
be considered a fundamental reference method because it is judged to be free of systematic error. However, the precision of isotope dilution inductively coupled plasma mass spectrometry (IDICPMS) is generally an order of magnitude worse than ID analysis performed with thermal ionization mass spectrometry (TIMS), which can reach levels of precision approaching 0.05% when magnetic sector mass spectrometry instrumentation is used. Still, the potential for ID analysis using the ICPMS is tremendous, and this has been exploited for clinical purposes. Depending on the element, access to isotopic ratios can also provide valuable information on source identification. The significance of ICPMS will continue to grow in specialized reference laboratories and, as the cost of modern instrumentation decreases, it is likely to become the preferred technique in the future.

Selecting an appropriate analytical technique for clinical purposes will depend on the number and nature of clinical specimens received for analysis, the element(s) requested for analysis and the skill of the laboratory personnel. The type of specimen selected for analysis depends on the element and its chemical species, e.g. inorganic or organometallic. Typically, whole blood, serum, plasma or urine are used to assess trace element status or monitor exposure to toxic elements. Specimens such as tissue, hair, saliva, nails, feces are less frequently encountered, and are complicated by the need for extensive sample preparation before instrumental analysis can proceed. The use of such specimens is reviewed in more detail below. For clinical purposes, specific applications may be categorized on the basis of analyte and concentration since this almost always governs the selection of analytical method. The major essential elements from group 1, Na and K, that, together with Li, are normally measured in emission, and the major essential elements from group 2, Ca and Mg, that are usually measured in absorption, are shown together in Table 1. The essential trace elements Zn, Cu, Se and Cr together with the toxic elements Pb, Cd, Hg and As are grouped together under Table 2.

Figure 4 Number of laboratory participants in the Quebec Trace Elements Interlaboratory Comparison Program by element, matrix and analytical technique. (Data are taken from the first run of 1999.24)

In this document, there is some background discussion of the group 1 elements Na and K from a historical perspective, but more detailed discussion is limited to elements that are considered clinically significant, and that are measured by AAS. Figure 4 shows the number of laboratories participating in the Interlaboratory Comparison Program operated by Le Centre de toxicologie du Québec during early 1999. The Québec program is an international external quality assessment scheme for selected trace elements in clinical matrices.25 The number of participants varies according to the element and the matrix (blood, serum or urine) such that it is clear from Figure 4 that some analyses, e.g. blood lead, attract far more participants than do others, e.g. serum selenium. Using these data, it is possible to identify a panel of trace elements that are considered more clinically significant than others. Therefore, this document is primarily limited to the “major” elements of clinical and environmental significance (Ca, Mg, Zn, Cu, Pb, Cd, Al, Se, Cr, As and Hg) that are routinely measured by atomic spectrometry.

2 HISTORICAL BACKGROUND

Historically, FAES methods using air–propane were among the first to be used for routine clinical measurements, and the technique was referred to as ‘flame photometry’. During the 1960s, flame photometry was used successfully for the determination of Na and K in serum. Today, Na and K are routinely measured in serum by automated analyzers based on ion-selective electrode (ISE) potentiometry. Nonetheless, FAES remains the reference method for Na7 and K9 as described by the National Reference System for the Clinical Laboratory (NRSCL).26,27 and is also used to standardize direct ISE systems for Na and K.14 Apart from Na and K, Li has also been routinely measured with success by flame photometry, for therapeutic monitoring of the antipsychotic drug, LiCO₃. A reference method for serum Li is also available based on FAES.10

Development of clinical applications for the group 2 essential elements, Ca and Mg, was spurred by the advent of commercial FAAS instrumentation during the 1960s. The analytical conditions under which the major group 1 and group 2 elements are determined using flame atomization techniques are summarized in Table 1. Although the current trend in clinical laboratory medicine favors measurement of ionized Ca, as a better indicator of physiological status, measurements of total Ca are still regarded as clinically useful. Indeed, the application of FAAS for measuring total Ca in serum is considered a referee method.11 Magnesium is routinely
measured in serum and urine by FAAS. The physiological concentration of Mg is high enough to permit direct determination following a sample dilution up to 50-fold. FAAS is also the preferred method for the determination of Zn and Cu in clinical specimens. For serum Cu and serum Zn, sample dilutions of 1 + 3 to 1 + 9 have been used successfully with viscosity-matched calibration standards. The application of FAAS to the determination of Ca, Mg, Zn, and Cu in serum is discussed in more detail below.

One of the most significant developments in clinical applications of FAAS was the introduction of a microsampling accessory that improved analytical sensitivity for some volatile elements by 100-fold. The approach pioneered by Delves for the determination of blood lead was particularly successful, and is known as the Delves’ cup microsampling flame atomic absorption spectrometry (DCAAS) method. (28) Delves’ approach is to deposit a relatively small amount of whole blood (<100µL) into a nickel cup, dry it and then insert it into an air–acetylene flame. A hollow quartz tube is mounted directly above the flame and along the optical axis such that the source beam passes directly through the sample cell. A small hole at the center of the quartz tube permits analyte atoms and blood matrix components, liberated in the air–acetylene flame, to move directly into the heated quartz tube, where they are momentarily trapped, thus increasing their residence time in the optical path. The resultant transient atomic absorption signal is separated in time from nonspecific absorption due to the blood matrix. Further improvements of the Delves’ cup method have included integrating the absorbance signals, pretreating new nickel cups to improve precision and interfacing the instrumentation to a computer to permit semi-automated analyses. (29,30) A major advantage of the Delves’ cup method is that only a very small blood sample volume is required for analysis. This made mass screening of pediatric populations possible by collecting capillary blood specimens using skin puncture techniques. Although DCAAS was the method of choice throughout the 1970s and 1980s, it has been largely superseded by ETAAS, which is more easily automated and which, at least with modern instruments, requires less skill for routine operation.

ETAAS technology has evolved over the last two decades into a sensitive, robust and reliable tool for trace element measurements. In ETAAS, the concept of characteristic mass \(m_c\) is used to define sensitivity as the mass of the analyte that produces an integrated absorbance equal to 0.0044 s. The term characteristic mass is normally quoted in picograms and is analogous to the concept of characteristic concentration \(C_0\) that is used in FAAS to define sensitivity as the concentration of an analyte producing an absorbance of 0.0044 (1% absorption). Modern ETAAS technology is designed around the Stabilized Temperature Platform Furnace (STPF), a concept developed by Slavin and others since the 1980s. (31–33) The key aspects of the STPF approach are summarized in Table 3. With few exceptions, they can be applied successfully to almost all matrices and to all elements that are measured by AAS, with exception of Hg, which is measured by CVAAS. The L’vov platform is a key aspect for successful analyses because it significantly delays analyte atomization until the furnace has more fully achieved thermal equilibrium, thereby minimizing chemical interferences that can plague wall atomization methods. The advent of fast digital electronics provides better data acquisition systems that more faithfully record the transient absorption signals that typify ETAAS. While some still debate the use of peak absorbance measurements, most accept that integrated absorbance \(A_i\) is much less likely to be influenced by chemical or matrix interferences, and because precision is better with \(A_i\), detection limits are improved.

In clinical applications, the sample matrix can be quite troublesome, so methods must be carefully optimized to avoid problems. The use of modifiers, i.e. chemical compounds or other elements, that stabilize the analyte during either pyrolysis or atomization, or both, and can free the analyte from the matrix, thereby increasing production of ground state atoms, is considered mandatory for most clinical applications. High-quality pyrolytically coated graphite tubes are also considered an important requirement for successful analyses. Rapid heating of the furnace, and use of a gas stop feature that prolongs the residence time of atoms in the optical path, improve the sensitivity. Background correction is also mandatory and although Zeeman-effect systems are preferred for their simplicity and ruggedness, other systems also work well except in a few selected cases.

While ETAAS remains the technique of preference in most routine clinical laboratories, AES has re-emerged as a viable option in situations where rapid measurement of several elements is required, such as screening urine for toxic elements. Modern AES instrumentation typically

employs an ICP excitation source, which is viewed either radially or axially with respect to the optical bench (Figure 2). Advantages of ICPAES over FAAS include the capability for simultaneous multielement analysis and an extended linear range that obviates the need for re-dilution of samples that are above the calibration range. One of the limitations of ICP techniques is the difficulty associated with using nebulizers for introducing samples of high viscosity and high dissolved-solids content. This requires carefully matching the samples with the calibration standards and, for samples such as urine, a cross-flow nebulizer is used to accommodate the relatively high dissolved-solids content.\(^{34}\)

In clinical applications, biological matrices can be especially troublesome because of the increased opportunity for spectral interferences, a problem that plagues emission techniques. In some respects, ICPAES now competes with ICPMS as a multielement technique, but the latter has very much better detection limits. There are, however, some important limitations with ICPMS, especially instrumentation equipped with quadrupole mass analyzers that are unable to resolve isobaric or polyatomic interferences. Selected examples of isobaric or polyatomic species are reviewed below under clinical applications of ICPMS. For clinical laboratories that require the capability to measure several trace elements simultaneously, ICPMS is rapidly becoming the preferred technique. As more ICPMS instruments find their way into clinical laboratories, new applications are being developed. Significant among these is the coupling of separation techniques with ICPMS to permit trace element speciation. While speciation is still in its infancy, for some applications, determining inorganic and organic species in urine and blood is now well established.\(^{35,36}\) The development and application of trace element speciation techniques in clinical laboratory medicine is reviewed in more detail below.

### 3 SPECIMEN COLLECTION AND PREANALYTICAL ISSUES

#### 3.1 Contamination Control

In analytical chemistry, it is often stated that the quality of an analytical result is only as good as the sample collected. In trace element analysis, the concern with contamination errors is always present, although the depth of concern depends on the element measured. Contamination control begins with specimen collection. Selecting an appropriate specimen collection device is critical to success. Simply using standard blood collection tubes may appear convenient but contamination from uncertified tubes will render the results useless. Several manufacturers market blood collection tubes specifically for trace element analysis, and some certify tubes for specific element(s). Contamination may originate from the tube stoppers, e.g. Zn, the anticoagulant or even from the container material, e.g. Al in glass. Thus it is good practice to check that collection devices are free of significant contamination for the element(s) to be measured. Standard test protocols now exist for checking blood collection tubes for Pb contamination,\(^{37}\) and they are easily applied to other elements. Delves\(^{38}\) recommends using simple preparation procedures with minimum handling of body tissues, tissue fluids, excreta and diets for those trace element analyses for which contamination is the major problem.

Apart from contamination, other preanalytical variables may also affect the results of trace element analysis. Several authoritative reviews\(^{32,33,35,36}\) of preanalytical variables in trace element determinations are available that provide detailed information on specimen collection procedures and transportation to the clinical laboratory for analysis. Guidelines for collecting clinical samples for trace element analysis are provided by the International Union of Pure and Applied Chemistry (IUPAC) Commission of Toxicology\(^{39}\) and by the NCCLS.\(^{23}\)

#### 3.2 Standard Precautions

When clinical specimens of human origin are submitted for analysis, the analyst is faced with a very different situation compared to environmental samples. Because it is often impossible for the analyst to know which are infectious, all clinical specimens should be treated as if potentially infectious. In the US, the Centers for Disease Control and Prevention (CDC) provides “Standard Precautions” guidelines for preventing the transmission of infectious disease for health care workers.\(^{40,41}\) Other organizations have also issued specific guidelines for laboratory workers exposed to infectious disease transmitted by blood, body fluids and tissues.\(^{42}\) These guidelines cover use of protective gloves and biohazard hoods, decontamination and clean-up procedures. Recently, Moreton and Delves\(^{43}\) discussed some specific biohazard concerns that arise when biological fluids are nebulized into ICPMS instrumentation. The generation of aerosols containing potentially infectious material is a particular concern with all nebulization techniques, including FAAS, ICPAES and ICPMS. These authors recommend adding a commercial virucidal disinfectant (Virkron) to all high-risk biological samples, and then subtracting the blank value for the 13 elements found in this product. They report the successful determination of Hg in urine by ICPMS, and Cu and Zn in serum by FAAS using this approach.
3.3 Specimen Selection

The specific body fluid, or tissue, that is sampled for analysis depends on the analyte that is to be measured, and the purpose for which the test result will be used. Typically, serum, plasma, whole blood or urine is collected for trace element analysis by atomic spectrometry. Whole blood specimens are preferred for those elements, e.g. Pb and Cd, that are concentrated within the erythrocytes or red blood cells (RBCs) and that, following exposure, remain within the blood compartment for some time, and are said to have biological residence times of the order of at least several weeks. Whole blood must be preserved with an anticoagulant to prevent clot formation and, of the various anticoagulants available, ethylenediamine tetraacetic acid (EDTA) salts or heparin are used. While heparinized blood can form fibrin clots more readily, trace element-free EDTA salts are difficult to locate.

The terms serum and plasma are often used interchangeably, and are sometimes mistakenly assumed to be the same specimen. While either serum or plasma can be used to assess trace elements status, they are biochemically different specimens. The differences between them can be analytically important (see aluminum below). When a serum or plasma specimen is required, it is important to separate it from the clot or RBCs as quickly as possible to prevent leakage of the RBC-bound element. Care must be taken to assure that exogenous contamination does not occur during the separation process. Several up-to-date documents are available that provide recommended sample/specimen collection guidelines for trace element analysis. The IUPAC Commission on Toxicology’s sample collection guidelines for trace elements in blood and urine provide protocols for collecting whole blood, serum or plasma, packed cells or erythrocytes, and urine for the determination of Al, As, Cd, Cr, Co, Cu, Pb, Li, Mn, Hg, Ni, Se and Zn. Recommended guidelines for the control of preanalytical variation in trace element determinations are also available from the NCCLS in the United States. The NCCLS guidelines include sample collection protocols for trace element analysis, which is defined as a body content of 0.01–100 µg g⁻¹, or 10 µg L⁻¹–10 mg L⁻¹, and ultra trace element analysis, which is defined as a body content <0.01 µg g⁻¹, or <10 µg L⁻¹.

Urine is widely regarded as an inferior indicator of trace element status except for a few elements such as Hg, As and Cr, which are so rapidly cleared from the blood compartment into the urine that blood concentrations do not adequately reflect recent exposure. While it is clearly more convenient and less invasive to collect spot urine specimens, urine analyte concentrations do not always correlate as well as serum or whole blood measurements, even when urine is corrected with a creatinine measurement, or when urine is collected as a timed specimen, e.g. 24 h.

In some situations, capillary blood collected by skin puncture, i.e. via fingerstick or heel stick, is desirable for screening purposes especially in pediatric populations, where, in the absence of a trained phlebotomist, venipuncture is difficult to perform. The choice of capillary blood will affect the selection of analytical technique because of the relatively small blood volumes (150–300 µL) that are typical of such specimens. Contamination errors with capillary specimens are always a concern, but for childhood lead screening purposes, the frequency of contamination errors can be held to around 5% if a rigorous cleaning protocol is adopted.

3.4 Tissues

It is uncommon for routine clinical laboratories to receive tissues for trace element analysis. In most situations, the specimen would be referred to a specialized reference laboratory for analysis. Tissue biopsies are difficult to perform without contaminating the specimen with the elements typically found in stainless steel. Liver biopsies are analyzed for copper in diagnosing Wilson’s disease (see section 5.4). Use of hair and nails are generally considered unreliable indicators of trace element status except, perhaps, in a few cases such as Hg and As poisoning. In the case of As, hair and nails have been used for forensic purposes to investigate arsenic intoxication. One of the major limitations of hair and nails is the extent to which the specimen is compromised by contamination. Although elaborate procedures have been devised for sampling these specimens, it is difficult to distinguish between exogenous environmental contamination and removal of endogenously bound elements that may be leached during a preanalytical washing procedure. The use of saliva and sweat specimens for assessing trace elements status is even more dubious and little information exists to validate these specimens.

4 UNITS FOR ELEMENT CONCENTRATIONS IN CLINICAL SAMPLES

A variety of units is used to report element concentrations in clinical samples. While much of the clinical laboratory community throughout the world uses substance (nmol L⁻¹ or mmol L⁻¹) concentrations, there is no such consensus within the US where a myriad of mass (µg L⁻¹, mg L⁻¹, µg mL⁻¹, ng mL⁻¹, ppm, ppb, etc.) concentrations are more frequently used. Mass concentration units are also frequently preferred within the analytical laboratory.
5 SINGLE ELEMENT CLINICAL APPLICATIONS OF ATOMIC ABSORPTION SPECTROMETRY

5.1 Calcium in Serum and Urine

Calcium is a major essential element from group 2 of the periodic table (alkaline earth elements) and is found at high concentrations in every compartment of the body. FAAS is considered a referee method for the determination of serum Ca because of its excellent sensitivity, freedom from interferences, and its traceability to reference standards. The FAAS technique measures “total” Ca in serum regardless of the element’s chemical binding. However, most routine clinical laboratories measure total serum Ca by photometric methods, and some use potentiometric ISE technologies. Some ISE technologies are designed to measure only the “free” or unbound Ca fraction in serum or plasma. The unbound Ca is also referred to by some as “ionized” Ca, but all serum calcium exists as the Ca\(^{2+}\) ion. Approximately 46% of Ca in serum is unbound, the remainder is bound to plasma proteins and complexed with other ligands. Some have argued that measurements of “ionized” Ca are physiologically more meaningful than total Ca, but a thorough discussion of this specific issue is beyond the scope of this text. The preferred specimen for total Ca measurement is either serum or heparinized plasma. Use of EDTA or oxalate anticoagulants is inappropriate since they bind Ca. In some situations, when urinary Ca is measured, hydrochloric acid is added to the collection container to prevent precipitation.

Calcium can be determined in an air–acetylene flame using any standard AAS instrumentation. Recommended analytical details are given in Table 1, and are based on the original National Bureau of Standards method published by Cali et al. Serum or plasma is separated from RBCs and diluted by a factor of 50 with diluent. Viscosity differences between serum or plasma and aqueous standard solutions may lead to a matrix effect with some nebulizer arrangements in FAAS. If this is a problem even with a dilution factor of 50, then matrix-matching the calibration standards is required. Typically, glycerol is added to the calibration standards to match viscosity, and a releasing agent is added to standards, controls and samples to prevent chemical interferences from phosphate, a natural component of biological materials. Phosphate binds Ca, forming a stable compound that does not dissociate in the air–acetylene flame, and causes a suppression in sensitivity. Lanthanum chloride is often used as a releasing agent for Ca, although strontium chloride may also be used.

5.2 Magnesium in Serum

Magnesium is another group 2 essential element that is found throughout the body at relatively high concentrations. Measurement of serum magnesium is important clinically for assessing magnesium deficiency (hypomagnesemia), which often results in neuromuscular impairment, e.g. hyperirritability, tetany and convulsions. In rare instances, increased serum Mg concentrations (hypermagnesemia) have been observed with dehydration, severe diabetic acidosis and Addison’s disease. The reference method for serum Mg is FAAS because of its selectivity, freedom from interferences and sensitivity. Serum specimens are separated from RBCs as quickly as possible since the Mg content of erythrocytes is greater than that of serum. In some situations, urine specimens are also analyzed to monitor Mg clearance. The FAAS method for serum Mg is straightforward and well established. Serum is diluted by a factor of 50 with a solution containing NaCl (2.8 mM), KCl (0.1 mM), to reduce ionization interferences, and LaCl\(_2\) releasing agent to reduce interferences from phosphate. Viscosity effects may be corrected by adding glycerol to the calibration standards. Diluted samples are aspirated directly into an air–acetylene flame, and Mg is determined at the 285.2-nm line with a Mg HCL.

5.3 Zinc in Serum

Zinc is well established as an essential trace element for normal healthy growth. It is required by numerous metalloenzymes including carbonic anhydrase, alkaline phosphatase and carboxypeptidase. Zinc deficiency has been recognized in humans since the 1960s, and is
associated with growth retardation, impaired wound healing and dermatitis. Serum or plasma Zn measurements are considered the best single choice of test to assess deficiency. Serum must be collected in tubes certified for trace element analyses since Zn contamination is particularly troublesome, with collection tube stoppers being a known source of contamination.

The preferred method for serum zinc is FAAS, which has ample sensitivity and good precision (detection limit ~ 1 µg L\(^{-1}\)), and rapid throughput. Some\(^{50}\) have used ETAAS to measure Zn in plasma and peripheral blood cells. The application of FI or pulsed-nebulization techniques coupled with FAAS is particularly attractive since sample volumes as low as 10–100 µL can be accommodated.\(^{51,52}\) Generally, samples and standards are matrix-matched for acid content and for viscosity. Serum is diluted by a factor of 5, and Zn is determined in an air–acetylene flame at the 213.9-nm line. Pizent and Telisman\(^{19}\) describe a FAAS method for serum Zn in which samples are diluted 1:9 with 6% aqueous butan-1-ol. Calibration is linear up to 15 mg L\(^{-1}\) and a detection limit of 0.78 µg L\(^{-1}\) is reported.

### 5.4 Copper in Serum and Urine

Copper is an essential element and, as a d-block element (Figure 1), its biochemistry is dominated by Cu\(^{2+}\) (d\(^{10}\)) complexes with various proteins such as ceruloplasmin and superoxide dismutase. Approximately 90% of serum Cu is bound to ceruloplasmin, with the remainder bound to albumin or amino acids, or other copper enzymes. Serum Cu is normally used to diagnose cases of copper deficiency due to malnutrition or malabsorption, or due to Menkes’ disease, a genetic disorder that is characterized by the appearance of “steely hair” and is often referred to as “kinky hair syndrome”.

Serum Cu is also used to diagnose Cu toxicity due to occupational or environmental exposures, or due to Wilson’s disease, a genetic defect in Cu metabolism that is characterized by Cu accumulation, i.e. Cu overload, in the liver, brain, kidneys and cornea. In cases of Wilson’s disease, liver biopsies are analyzed for Cu content. When collecting liver biopsies for Cu determination, care should be taken to prevent contamination from metal instruments. Penicillamine, a chelation drug, is used to promote excretion of excess Cu into the urine, which is analyzed for Cu content. For serum (or plasma) Cu measurements, the blood collection tubes should be certified for trace element measurements.

The analytical method most commonly used for serum Cu measurements is FAAS, although ETAAS and ICPMS are also used. Most manufacturers of FAAS instrumentation provide standard protocols for serum Cu measurement based on matrix-matched standards, and determination in an air–acetylene flame at the 324.8-nm line. FI techniques coupled to FAAS have also been used to measure serum Cu.\(^{53}\) Pizent and Telisman\(^{19}\) describe a FAAS procedure for serum Cu in which samples are diluted 1:9 with 6% aqueous butan-1-ol. Calibration is linear up to 15 mg L\(^{-1}\) and a detection limit of 1.27 µg L\(^{-1}\) is reported. A detailed standard operating procedure for serum Cu by FAAS is also described by Alcock.\(^{54}\) This method may also be used to determine Cu in urine at the relatively high concentrations found in copper overload cases, i.e. Wilson’s disease, and following a penicillamine challenge. Where FAAS detection limits are a concern, such as in estimating urine Cu at normal concentrations, either ETAAS or ICPMS is preferred. Alcock\(^{54}\) also described an ETAAS procedure for serum and urine Cu that is based on the STPF approach.

Other workers have also been successful in using ETAAS for Cu determinations in clinical samples. Lapointe and LeBlanc\(^{55}\) described an ETAAS procedure for the determination of Cu in serum or plasma based on the STPF concept with Zeeman-effect background correction. Serum or plasma samples are diluted 1:50 with 0.4% Triton X-100, 1% NH\(_4\)H\(_2\)PO\(_4\) and 0.06% Mg(NO\(_3\))\(_2\). Calibration with aqueous standards was linear up to 2.5 mg L\(^{-1}\) and a detection limit of 60 µg L\(^{-1}\) was reported, with a characteristic mass of 7 pg. Method validation using proficiency materials from the Quebec Intercomparison program for trace elements is described. Schmitt\(^{56}\) also used ETAAS to determine Cu (and Zn) in plasma and peripheral blood cells, and reported finding elevated platelet Cu levels in renal insufficient patients.

It is generally agreed that there are age- and sex-specific reference intervals for serum Cu (Table 2). Thus, it is advisable to consult an authoritative source for interpreting serum Cu levels.\(^{52}\)

### 5.5 Lead in Blood and Urine

Lead is a nonessential element that is widely recognized as a serious environmental health problem following many centuries of industrial use. It is a particular health problem for very young children, who are exposed to environmental lead through normal hand-to-mouth activities, and who absorb lead much more efficiently than adults via their gastrointestinal tracts. Since more than 90% of Pb in the blood compartment is bound to the RBCs, whole blood Pb measurements are preferred for diagnosing Pb poisoning cases. Adults are more likely to be exposed either in occupations that involve Pb or Pb products, or in hobbies and recreational activities that involve Pb, e.g. stained-glass art work, illegal moonshine production, etc. Capillary blood obtained via skin puncture is acceptable for screening purposes, but only venous blood should be used for diagnostic and treatment purposes.
Either heparin or EDTA anticoagulant may be used to preserve whole blood specimens, although the latter is preferred because it permits longer storage time. In the US, urine Pb measurements are used for long-term monitoring of workers occupationally exposed to lead because collection is less invasive, and it does not require a phlebotomist. In European countries, however, long-term monitoring of lead workers is based on blood lead measurements. Urine Pb measurements are also used in the CaNa₂EDTA challenge test to assess lead mobilization, but this test is considered less useful today, at least in children. Special attention to contamination errors is important because industrial uses of lead have resulted in significant environmental contamination. Serum or plasma Pb measurements have been attempted in epidemiological studies, but normal concentrations are generally below the method detection limit by ETAAS, so ICPMS with electrothermal vaporization (ETV) is appropriate. Determination of Pb in bone is important in toxicology research studies, with most bone specimens obtained post-mortem. Measurement of Pb in other samples, e.g. nails, is not considered reliable for routine clinical purposes because of contamination concerns and the lack of robust validation resources.

Today, the preferred method for blood lead is ETAAS. Modern methods, based on the STPF approach, have culminated in a consensus method for blood lead that has been validated with various instruments with different background correction systems, and is recommended for use in clinical laboratories. The method involves a simple 1:9 dilution of whole blood, with a phosphate modifier, Triton X-100 and nitric acid, followed by platform atomization and integrated absorbance measurements at the 283.3-nm line. Urine lead measurements are also possible using the same dilution and method, although the method detection limit does not support urine lead measurements at normal concentrations.

The reference range for blood lead is population-dependent. In 1991, the US geometric mean blood Pb level for the general population was reported to have fallen to 2.8 µg dL⁻¹ (0.13 mol L⁻¹), and to 3.6 µg dL⁻¹ (0.17 mol L⁻¹) in children aged 1–2 years. In 1994, the geometric mean blood Pb fell even further to 2.3 µg dL⁻¹ (0.11 mol L⁻¹) and to 3.1 µg dL⁻¹ (0.15 mol L⁻¹) in children. Public health agencies consider a blood lead level above 10 µg dL⁻¹ (0.48 mol L⁻¹) in children harmful, and above 40 µg dL⁻¹ (1.93 mol L⁻¹), treatment with chelation drugs is indicated. Interestingly, occupational exposures up to 40 µg dL⁻¹ in adults are tolerated in the US in spite of evidence of biochemical effects on the hematopoietic system.

The reference range for urine lead in the US population indicates the geometric mean is 2.08 µg L⁻¹ with the 95th percentile at 6.07 µg L⁻¹ (0.03 mol L⁻¹). This is considerably lower than mean urine Pb levels of 14.6–17 µg L⁻¹ (0.07–0.08 µmol L⁻¹) reported for European populations.

### 5.6 Cadmium in Blood and Urine

Cadmium is a nonessential toxic metal that has many industrial and commercial uses. It is taken up by plants, particularly vegetables grown in contaminated soils, resulting in exposures to human populations. Tobacco plants are particularly efficient accumulators of Cd, such that tobacco smokers are more exposed to Cd than are nonsmokers. Cadmium exposure is usually assessed by measuring its concentration in whole blood since it is largely taken up into RBCs. Urinary Cd is used for long-term monitoring of occupational exposure in adults. Contamination errors can occur through using supplies and reagents that have not been prechecked for Cd content. Colored plastic pipette tips are a known source of Cd contamination.

The method routinely selected for measuring Cd in blood or urine is ETAAS. Current experience indicates that ETAAS methods based on the STPF approach are successful, with Zeeman-effect background correction systems preferred. D’Haese et al. report that it is possible to overcome the difficulties experienced with continuum-based correction systems by using a Mo-coated tube/platform. The excellent sensitivity of ETAAS (mₒ = 0.4–1.3 pg) provides detection limits on the order of 0.01–0.1 µg L⁻¹. The sensitivity for Cd by AAS is so good that FAAS methods have been developed based on slotted tube atom trapping and FI techniques. An exhaustive review of AAS applications for determination of Cd in biological samples by AAS is available, and covers the literature up to 1993. The consensus from the literature is that with modern ETAAS instrumentation equipped with Zeeman background connection, direct analysis is feasible using phosphate and Mg modifier, peak area measurements and platform atomization, i.e. the STPF approach. With older instrumentation, it may be necessary to perform additional sample pretreatment, such as protein precipitation and/or digestion with nitric acid.

Reference ranges for Cd in blood are different for nonsmokers and smokers such that for the latter, blood Cd is double that of the former. A blood Cd value in excess of 10 µg L⁻¹ (0.089 µmol L⁻¹) indicates significant exposure.

### 5.7 Aluminum in Serum, Plasma and Dialysate

Aluminum is another nonessential metal that is ubiquitous in the environment, so it is hardly surprising...
that it is found in appreciable amounts in almost every compartment in the human body. Its ubiquitous nature in the environment also presents a formidable challenge to analysts who must struggle with contamination control.

The significance of aluminum measurements in clinical situations became evident as a result of advances in the medical management of patients with end-stage renal disease through treatment with hemodialysis. The accumulation of Al in dialysis patients results in aluminum loading in bone and brain tissues, which leads to a fatal neurological syndrome called dialysis dementia. Historically, the most important source of aluminum in the development of dialysis dementia was tap water, treated with alum, and used for preparation of dialysis fluids without any further treatment. Aluminum used to treat hyperphosphatemia was a much smaller input although still important. Now that water supplies are treated to remove aluminum, the principal source of aluminum is from the administration of aluminum hydroxide, used to treat hyperphosphatemia in end-stage renal disease. Dialysis centers must be aware that the Al content of the water and dialysis fluid is within acceptable levels. For monitoring Al levels in dialysis patients, a serum (or plasma) specimen must be obtained for the analysis. In the US, urine Al is sometimes used to monitor exposed workers, but the clinical value of such measurements is debatable, and specimen contamination in occupational settings is much more serious.

In most situations, the preferred analytical method for routine serum Al determination is ETAAS, which has the required sensitivity and precision to meet the detection limits necessary to report concentrations above 50 µg L\(^{-1}\) (1.85 µmol L\(^{-1}\)). With modern instrumentation and the STPF approach, it is considered no longer necessary to remove plasma proteins by precipitation prior to analysis. Direct analysis, following simple dilution with a Mg(NO\(_3\))\(_2\) matrix modifier containing Triton X-100 plus nitric acid, is straightforward and does not require the method of standard additions. Aluminum can be determined either at the 309.3-nm line (\(m_0 = 11 \text{ pg}\)) or at the 396.2-nm line (\(m_0 = 14 \text{ pg}\)), although the latter has a greater linear dynamic range.\(^{[73]}\) The use of Ca(NO\(_3\))\(_2\) modifier instead of Mg(NO\(_3\))\(_2\) is preferable when analyzing bone and tissue digests and can be used with serum and dialysate samples.\(^{[15]}\) But addition of Ca(NO\(_3\))\(_2\) to plasma samples results in rapid protein precipitation, which makes the analysis troublesome. The general consensus is that it is preferable to use Mg(NO\(_3\))\(_2\) modifier for serum, plasma and dialysate specimens. Using nitrogen as the purge gas causes a loss of sensitivity for Al, so argon gas should be used.

The normal clinical range for serum Al is less than 10 µg L\(^{-1}\) (0.37 µmol L\(^{-1}\)), and concentrations up to 50 µg L\(^{-1}\) (1.85 µmol L\(^{-1}\)) are not considered toxic. Serum Al concentrations up to 100 µg L\(^{-1}\) indicate an increased Al intake, and at concentrations above 100 µg L\(^{-1}\) (3.70 µmol L\(^{-1}\)) the potential for Al toxicity exists and medical investigation is warranted.\(^{[76]}\)

### 5.8 Selenium in Serum

Selenium is an essential element that is a component of glutathione peroxidase, an enzyme that is involved in the antioxidant defense system. A group 16 (or group VI B) element, Se is classified as a nonmetal (Figure 1). Chronic Se deficiency is associated with cardiovascular disease in humans\(^{[77]}\) and with Keshan disease, an endemic cardiomyopathy that affects women and children in certain areas of China.\(^{[13]}\) Kashin-Beck disease is also found in China, and is linked to low Se status. Selenium toxicity is rare in humans but in animals (cattle and horses), it is characterized by a neurological dysfunction ("stargazers"). Nutritional assessment of Se status is by measuring Se in serum, but toxicity is assessed via urinary Se.\(^{[77]}\)

There are a variety of analytical techniques available for measurement of serum Se, including fluorimetry, AAS, ICPMS and neutron activation analysis (NAA). The latter technique is limited to facilities with access to neutron sources. Methods based on AAS can be categorized as either electrothermal atomization or HGAAS techniques. The latter, HGAAS, has been coupled to both ICPMS and AES instrumentation for determination of serum Se.\(^{[78]}\)

Methods using ETAAS have been developed for a wide range of instrumentation. Some analysts favor using an EDL as the radiation source, with determination at the 196.0-nm line. However, while the EDL gives a more intense emission, these lamps are not convenient for use with many commercial instruments and HCLs are widely used without too great a problem. The optimum modifier is still a matter of debate among the experts with some recommending Ni\(^{[79,80]}\), others Pd,\(^{[81]}\) sometimes with a reducing agent such as ascorbic acid\(^{[82]}\) or as a Pd/Mg\(^{[22,83]}\) mixed modifier, while others have used Cu and Fe.\(^{[84]}\) Some experts\(^{[17]}\) recommend air (oxygen) ashing in situ prior to atomization to reduce carbonaceous build up. Van Dael et al.\(^{[22]}\) describe a standard additions method for serum Se using a transversely heated graphite furnace (THGA) with a longitudinal Zeeman background correction system. Serum (100 µL) is diluted with 200 µL 0.25% Triton X-100, 200 µL water and 500 µL Se standard, and 20 µL of the diluted specimen is injected on to the platform, along with 10 µL modifier (15 µg Pd + 10 µg Mg). Calibration is linear up to 25 µg L\(^{-1}\), and a detection limit of 27 pg is reported. A comprehensive critique of the various modifiers proposed for the serum Se assay covering over 200 papers up to the early 1990s.
Se(IV) is reacted with NaBH₄ in solution to form gaseous quantitation. An IUPAC interlaboratory round-robin the gas phase. The resultant transient signal is captured for decomposes to form ground state atoms of Se and H₂ in H₂Se, which is then directed into the optical path of an accomplished using hydrochloric acid at 95–100 °C. The Se(IV) oxidation state (selenite). This is generally selenium in the serum must be reduced (or oxidized) to is easily decomposed into ground state atoms. First, all technique is based on the generation of H₂Se gas, which for Se in biological samples are provided by Tsalev. The quartz tube may be heated either electrically or by a flame. Upon entering the heated tube, H₂Se rapidly decomposes to form ground state atoms of Se and H₂ in the gas phase. The resultant transient signal is captured for quantitation. An IUPAC interlaboratory round-robin conducted more than a decade ago for Se determination in serum and urine with acid digestion and HGAAS showed good interlaboratory agreement.

Van Dael et al. compared their THGA method for serum Se (described above) with a FI/HGAAS method, based on work published by Weltz and Shubert-Jacobs using direct calibration with peak height measurements. Their reported detection limit is 59 pg. Both methods gave acceptable values for CRMs. Weltz and Stauss investigated interferences from hydride-forming elements on selenium in HGAAS with a heated quartz-tube atomizer. They compared two instrumental arrangements: a Perkin–Elmer model MHS-20 Hg/hydride batch system, and a Perkin–Elmer model FIAS-200 FI system. A deficiency of radicals was cited as the main reason for the low tolerance towards other hydride-forming elements in the batch system. However, there were no problems in the FI system. With conditions optimized, tolerance limits were one to two orders of magnitude higher than with the batch system. More detailed discussions of HGAAS methods for Se in biological samples are provided by Tsalev.

Reference intervals for serum Se are age- and geography-dependent. Values for adults range from 109 to 181 µg L⁻¹ (1.38–2.29 µmol L⁻¹) for British Columbia to 103.5±21.3 µg L⁻¹ (1.31±0.27 µmol L⁻¹) for the UK.

5.9 Chromium in Urine

Chromium is a transition metal (d⁴) that is now widely accepted as an essential trace element required for normal healthy growth. Its precise biochemical function remains a matter of debate, but in the +3 oxide state it is believed to be involved in the metabolism of carbohydrate and lipids. In the +6 oxidation state, i.e. as chromate, it is known to be highly toxic, such that exposure to chromate dust is known to cause lung cancer.

Measurement of Cr in clinical samples is usually for occupational monitoring purposes. In such cases, a spot urine specimen is typically obtained. Serum Cr is occasionally measured for research purposes, but because serum Cr concentrations are so low, ranging from 0.04 to 0.39 µg L⁻¹ (0.77–7.5 nmol L⁻¹), care should be taken to avoid contamination from stainless steel needles. Plastic blood collection tubes certified for trace element analyses should be used. The method of choice for measuring urinary Cr is ETAAS, and the procedure described by Veillon et al. was one of the first to document true normal levels. Chromium is usually determined at the 357.9-nm line, which can be troublesome for continuum-based correction systems both because the intensity of the D₂ source is low, and the background intensity from the urine and modifier matrix is large and structured at this wavelength. Use of high quality pyrolytically coated graphite is also particularly important with this analyte. Paschal and Bailey’s method is a classic STPF approach with Zeeman background correction. They used a simple dilution of urine with nitric acid and Triton X-100 as matrix modifier, and reported a detection limit of 0.5 µg L⁻¹. Burguera et al. evaluated several modifiers and two ETAAS systems for the determination of Cr in urine. They compared a longitudinally heated furnace (HGA), with D₂ background correction, to a THGA with a longitudinal Zeeman background correction system. Urine (20 µL) and modifier (10 µL) were deposited on the platform sequentially. Results show that, of the five modifiers evaluated, including Eu, Mg(NO₃)₂, Pd, Eu–Pd and Ni, only Eu was effective with the HGA–D₂ arrangement. However, the THGA arrangement was much less troublesome in relation to background correction, and Mg(NO₃)₂ was selected for routine work. Both the HGA, with Eu, and the THGA, with Mg(NO₃)₂, methods were validated with Standard Reference Material (SRM) 2670 and Seronorm control materials. Detection limits reported for Cr in urine are 0.03 µg L⁻¹ (HGA–D₂) and 0.05 µg L⁻¹ (THGA–ZL).
Reference intervals for urine Cr are reported in the range 0.05–0.58 µg L⁻¹ (0.962–11.15 nmol L⁻¹), and 0.04–0.39 µg L⁻¹ (6.769–7.50 nmol L⁻¹) for Cr in serum. The geometric mean for urine Cr in the US population is 0.13 µg L⁻¹ (2.50 nmol L⁻¹) with the 95th percentile at 0.70 µg L⁻¹ (13.46 nmol L⁻¹).

5.10 Arsenic in Urine

Arsenic is a clinically significant element because of its distribution in the environment and its relative toxicity. The most common exposures are either occupational or via consumption of contaminated seafood, although intentional poisonings do receive abundant coverage in the news media. The specimen of choice for exposure assessment is a 24-h urine collection. Although As is largely excreted in urine as dimethylarsenic acid (DMA), measurement of total As is routinely performed for clinical diagnostic purposes. Determination of specific As species is discussed in more detail below.

For laboratories with considerable experience with HGAAS, this is the method of choice for urinary As determination. In HGAAS, arsenic gas (AsH₃) is generated by the reduction of inorganic As with NaBH₄ solution. The arsenic gas is swept into a heated quartz absorption tube, where it is reduced to ground state AsH₃ by a 1-mL Bond-Elut cartridge with HNO₃–ethanol (1 : 10). The eluate is heated with K₂Cr₂O₇ and HNO₃, and then H₂SO₄. The mixture is cooled, H₂O₂ is added and then the mixture is reheated. After cooling, the mixture is treated with KI in HCl followed by mixing with HCl and NaBH₄ in NaOH solution. Detection limits of 0.1–0.2 µg L⁻¹ are obtained.

The application of ETAAS with continuum background correction systems is known to be troublesome in urinary As determination because of spectral interferences at the 193.7-nm line, volatilization losses and species-specific behavior. However, ETAAS methods based on the STPF concept with Zeeman instrumentation are much more successful. Paschal et al. described a FI/HGAAS method for measurement of urinary As and its metabolites in which urine is applied to a 1-mL Bond-Elut cartridge with HNO₃–ethanol (1 : 10). The eluate is heated with K₂Cr₂O₇ and HNO₃, and then H₂SO₄. The mixture is cooled, H₂O₂ is added and then the mixture is reheated. After cooling, the mixture is treated with KI in HCl followed by mixing with HCl and NaBH₄ in NaOH solution. Detection limits of 0.1–0.2 µg L⁻¹ are obtained.

5.11 Mercury in Urine and Blood

Mercury is a nonessential, toxic element that has numerous industrial applications. Exposure to toxic levels of Hg is most frequently encountered in occupational settings. However, low-level exposures can also result from consuming contaminated seafood, which not only accumulates Hg, but enables its biotransformation into organomercury species. In some cultures, Hg-containing compounds are used for medicinal purposes, and this can lead to Hg poisoning.

The preference for assessing exposure to inorganic Hg (Hg⁰) is a 24-h urine specimen because Hg⁰ is cleared from the blood compartment quite rapidly. Whole blood is preferred when exposure to organomercury compounds is suspected. Determination of Hg in blood or urine by AAS is accomplished using the cold vapor technique, in which Hg is reduced to ground state atoms by a reagent such as SnCl₂, and the gaseous atoms are swept into a quartz cell mounted in the optical path of the AAS instrument. Measurement is at the 253.7-nm resonance line. In one of the earliest applications, Magos described the selective determination of Hg⁰ and methylmercury (Me–Hg) in undigested biological samples by AAS and, later, Magos and Clarkson described the determination of total and inorganic Hg species in blood using CVAAS. They used L-cysteine to bind Hg⁰, which was then subsequently treated with SnCl₂ to liberate Hg atoms. Total Hg was measured by directly treating the sample with a mixture of SnCl₂ and CdCl₂; organic Hg was estimated as the difference between the total and the inorganic fractions. Littlejohn et al. modified Magos’ CVAAS method further for measuring total and inorganic Hg in urine, and compared it against NAA. They reported a CVAAS detection limit of 0.82 µg L⁻¹ for Hg in urine. Toffaletti and Savory used NaBH₄ as the reducing agent for the determination of total Hg in urine by CVAAS with a detection limit of 2 µg L⁻¹. However, this procedure does not distinguish between inorganic and total Hg. Sharma and Davis also used NaBH₄ reduction to measure total Hg in blood. A similar detection limit (1.15 µg L⁻¹) was reported. Compared to SnCl₂ reduction, the advantages of NaBH₄ are that it is simple (one
The introduction of on-line microwave-assisted digestion equipment coupled with AAS instrumentation has opened up new possibilities for both CVAAS and HGAAS. Several publications\(^\text{[21,104]}\) explore the application of on-line microwave sample pretreatment for the determination of Hg in urine. Weltz et al.\(^\text{[21]}\) described the use of such an arrangement with FI to measure urinary Hg. Urine is mixed off-line with 0.5% K\(_2\)Cr\(_2\)O\(_7\) in HNO\(_3\) (1:1) and, in the autosampler vessels, with 1 to 2% (v/v) of a bromination reagent (2.23% KBrO\(_3\)-8% KBr) before introduction into a carrier stream of 0.3% HCl and passage to the microwave digester. For the lower concentration range (ng L\(^{-1}\)), H\(_2\)O rather than HCl is used. The effluent from the digester (50–90 \(^\circ\)C) is merged with a reductant containing NaBH\(_4\) and NaOH plus an antifoaming agent, and passed through a hydride manifold and a gas-liquid separator before filtration and CVAAS. A detection limit of 10 ng L\(^{-1}\) is reported based on a 10-mL urine sample.

Guo and Baasner\(^\text{[105]}\) describe a similar FI/CVAAS method for Hg in blood, in which 500 \(\mu\)L of whole blood is mixed off-line with Triton X-100, and mixed with a bromination reagent. The sample is mixed with HCl on-line, passed through the digester and further oxidized with KMnO\(_4\), followed by reduction with NaBH\(_4\)-NaOH and Hg measured by CVAAS. Calibration was linear up to 20 \(\mu\)g L\(^{-1}\) with a detection limit of 1 \(\mu\)g L\(^{-1}\).

Nixon et al.\(^\text{[106]}\) described a CVAAS procedure for the determination of inorganic, organic and total Hg in blood and urine. The method is based on a commercial automated FI system with CVAAS. For Hg\(^0\) measurement, either 500 \(\mu\)L whole blood or 1 mL urine are combined with HNO\(_3\), H\(_2\)SO\(_4\) and KMnO\(_4\) off-line, vortexed and centrifuged. For total Hg, either 500 \(\mu\)L of whole blood or 1 mL of urine are combined with HNO\(_3\), H\(_2\)SO\(_4\) and K\(_2\)S\(_2\)O\(_8\) off-line and heated at 95 \(^\circ\)C. The samples are analyzed by FI/CVAAS with SnCl\(_2\) reduction and HCl for the sample probe wash solution. Calibration was linear from 0.5 to 25 \(\mu\)g L\(^{-1}\). A commercially available FI system with on-line digestion coupled to CVAAS for determination of total and inorganic Hg in whole blood was also described by Chen et al.\(^\text{[107]}\). Inorganic Hg is measured following reduction with SnCl\(_2\) and without using the microwave digestion system. Total Hg is determined using a modification of the fumigation procedure described by Guo and Baasner\(^\text{[105]}\) including microwave-assisted digestion followed by NaBH\(_4\) reduction. Organomercury concentrations are calculated as the difference between the two. They report detection limits of 0.45 \(\mu\)g L\(^{-1}\) and 0.14 \(\mu\)g L\(^{-1}\) for Hg\(^0\) and total Hg, respectively.

Normal concentrations of Hg in blood and urine are complicated by the methodology used and whether Hg\(^0\) or total Hg are being reported. For total Hg, recent reports\(^\text{[23]}\) suggest normal levels are <5 \(\mu\)g L\(^{-1}\) (<25 nmol L\(^{-1}\)) for blood, and <20 \(\mu\)g 24 h\(^{-1}\) (<100 nmol L\(^{-1}\)) in urine.

### 6 LITERATURE REVIEW

#### 6.1 General Reviews of Trace Element Analysis of Biological Systems with Atomic Absorption Spectrometry Techniques

Several reviews of clinical applications of analytical atomic spectrometry are available to assist clinical laboratory personnel with the selection of appropriate methods for trace element analysis. Perhaps some of the most definitive texts on atomic absorption methods in occupational and environmental health are the series published by Tsalev and Zaprianov\(^\text{[108]}\) and Tsalev\(^\text{[109]}\) in 1984, and an updated edition by Tsalev\(^\text{[74]}\) in 1995 reporting progress over the 10-year interval. Volumes I\(^\text{[108]}\) and II\(^\text{[109]}\) focus on 34 selected elements that are of occupational and environmental health significance: Al, As, Au, Ag, Ba, Be, Bi, B, Cd, Cr, Co, Cu, Fe, Ga, Ge, Hg, In, Li, Mn, Mo, Ni, Pb, Pd, Pt, Ru, Sb, Se, Sn, Si, Sn, St, Te, Ti, V, Zn. In Volume III\(^\text{[74]}\) 21 new elements were added to bring the total number of elements covered up to 55. A wide variety of biological matrices are included for each element.

An excellent review published by Delves in 1987\(^\text{[110]}\) assesses the role of AAS in clinical analyses and compares it to other spectroscopic techniques, including plasma source mass spectrometry and atomic emission techniques. In his review, Delves also discussed the physical and ionization interferences that can occur with clinical samples in FAAS, and the control and elimination of chemical and physical interferences in ETAAS. Various approaches to background correction in AAS are reviewed with respect to clinical matrices, and include continuum, Zeeman-effect and Smith–Hietje arrangements. Pre-analytical issues are also discussed, especially contamination control.

Taylor\(^\text{[111]}\) presented a thorough review of clinical applications of FAAS in a volume devoted to the principles and applications of AAS. Sample preparation techniques, including simple dilution, protein precipitation, chelation with solvent extraction and acid digestion are reviewed in some detail. The review also covers devices, such as the slotted quartz tube, that were previously shown to improve sensitivity in the flame for Pb and Cd in blood and Cu and Zn in serum\(^\text{[72]}\). In the same volume on principles and applications of AAS, Delves and Shuttle\(^\text{[47]}\) critique ETAAS methods for analysis of body fluids and tissues. They address a number of problem areas with ETAAS methods for clinical samples.
including physical, chemical and spectral interferences, and contamination errors, and they also address several specific problems that are well known with clinical samples. For example, the problem of carbonaceous build-up on the L’vov platform that occurs with blood matrices is discussed. Delves and Shuttler recommend using an oxygen ashing phase as part of the furnace program, to overcome this problem. These authors also described special difficulties when analyzing urine samples, particularly irreproducible results that are evident with some specimens. Methods for the essential trace elements Zn, Cu, Fe, Se, Mn, Cr, Co, Mo, V and Al are reviewed individually, as are methods for therapeutic elements, Pt and Ag, and the nonessential toxic elements Pb, Cd, Ni, Be and Tl.

Extensive annual reviews on the analysis of clinical and biological matrices for the major, trace and ultratrace elements have been published since 1986 as Atomic Spectrometry Updates. These updates are an invaluable resource for the latest developments in the field since they include material presented at major conferences on analytical atomic spectrometry. The updates are structured to cover sample collection and pretreatment, including digestion procedures, and cover clinical applications of AAS, AES and ICPMS. In the most recent update, some 35 elements of clinical significance were reviewed separately. Occasionally, clinical applications of atomic spectrometry are reviewed in other analytical journals. Paschal reviewed the selection of spectroscopic method for the determination of toxic and essential elements, and discussed the collection and storage of samples with reference to two examples: Pb in blood and Tl in urine. Alcock presented a concise update on atomic spectrometric methods for clinical samples, reviewing the status of FAAS, ETAAS, ICPAES and ICPMS. In that review, Alcock noted the emergence of ICPMS in clinical applications as a unique tool among the arsenal of spectroscopic methods in its ability to discriminate between different stable isotopes of the same element where they exist. Savory and Herman discussed recent advances in instrumental methods for the measurement and speciation of trace metals in biological samples. Their review covers novel applications of ETAAS and the emergence of ICPMS for ultra-trace metal analysis, and methods for the intracellular localization of trace elements, which are beyond the scope of this text.

6.2 Clinical Applications of Inductively Coupled Plasma Atomic Emission Spectrometry

ICPAES is limited by its poorer sensitivity for some clinically significant elements, and by the need either to dilute blood and serum samples or to pretreat them to avoid physical interferences in the sample introduction arrangement. The performances of ICPAES and NAA were examined for their suitability in determining Al, Cd, Cr, Cu, Mg, Mn, V and Zn in human lung tissue. For ICPAES, samples were pretreated by ashing and the residue dissolved in nitric acid. Both ICPAES and NAA gave reliable results, although Al, Cd and V were troublesome. Direct determination of Ca, Cu, Fe, Mg, Mn and Zn in amniotic fluid samples was accomplished using ICPAES without the need for sample pretreatment and/or dilution. A sheath gas device and a matrix-matching calibration technique, where standards were prepared in 0.5% bovine serum albumin and 0.76% NaCl were used, and the results validated against National Bureau of Standards human serum. However, amniotic fluid samples had to be centrifuged before being introduced into the nebulizer. In a comparison between ICPAES and AAS, serum samples were analyzed for Zn, Cu, Fe, Mg, Ca, Na and K. Results of this study were that ICPAES yields slightly higher serum Cu, Mg, Ca and K, and lower serum Zn, Fe and Na values compared to AAS. Kimberly and Paschal describe an ICPAES method for rapidly screening urine specimens for up to nine elements including Se, As, Cr, Zn, Cd, Pb, Ni, Mn and Cu. Their method is based on a sequential scanning ICPAES instrument that utilizes a cross-flow nebulizer to handle the high dissolved-solids content of urine specimens. They used Y as an internal standard to correct for viscosity differences between calibration standards and undiluted urine specimens. Although the method was validated, the authors report difficulties with Cd, Se and Zn. Detection limits range from 2 µg L⁻¹ for Cd to 81 µg L⁻¹ for As.

Several workers have optimized ICPAES instrumentation to measure a single element in clinical matrices. Perhaps it is not surprising that, where single-element methods have been developed for clinical matrices, the element has invariably been either Al or Pb. Lyon et al. evaluated an ICPAES procedure for the determination of Al in serum, dialysate fluid and water, and validated it by comparison to an ETAAS method. Hu et al. also developed an ICPAES method for Al in biological materials, including human serum, but used an ETV device to deliver the analyte to the plasma. They used a polytetrafluoroethylene chemical modifier to produce a slurry, which was deposited in the furnace. The detection limit was 0.5 ng mL⁻¹ and the method was validated against CRMIs. A method for blood lead was developed for a capacitively coupled microwave-induced plasma (MIP) AES, in which a 5-µL blood sample is deposited, dried and ashed on a W electrode, and subsequently vaporized into the MIP. The method was validated with blood-based reference materials (RMs). Alvarado et al. also developed a
method for the direct determination of lead in blood using an ETV/ICPAES arrangement. A detection limit of 0.7 µg dL⁻¹ was reported. Recknagel et al.(135) devised a method for the determination of Se in serum by ICPAES, using an on-line wet-digestion procedure with hydride formation. The detection limit was 5.5 µg L⁻¹ with a linear range up to 500 µg L⁻¹. In addition to Se, Fe, Cu and Zn can be determined in the microgram per liter concentration range. Method validation included analysis of reference controls and a comparison with ETAAS for human serum samples.

6.3 Clinical Applications of Inductively Coupled Plasma Mass Spectrometry

6.3.1 Multielement Inductively Coupled Plasma Mass Spectrometry Analysis of Biological Samples

In the late 1980s, Lyon et al. evaluated ICPMS performance for multielement trace analysis in clinical chemistry. They conducted an interlaboratory round-robin in which ICPMS was compared with ICPAES and various AAS instrumentation for a plasma protein solution and a urine QC material. While polyatomic interferences occur with some elements by ICPMS, ICPAES has complex spectra and spectral overlap can be troublesome, while in ETAAS, under- or over-background correction can be problematic. Vaughan et al. also described using ICPMS in a semiquantitative mode as a rapid survey method for profiling trace elements in body fluids. At a 10-fold dilution, up to 13 elements can be detected in serum, and up to 15 elements in whole blood. These authors also reported difficulties with polyatomic interferences, specifically with Cr, Mn and V.

Although clinical applications of ICPMS are less numerous than in environmental and other fields, the appearance of affordable and compact instrumentation based upon an argon plasma and a quadrupole mass analyzer has opened the door for clinical laboratories to explore novel uses. In a 1993 review, Barnes discussed advances in ICPMS and its application in human nutrition and toxicology. The role that ICPMS can play in stable isotope tracer studies was examined and, in particular, its application to kinetic modelling studies. Barnes also concludes that ICPMS was likely to contribute to a wide range of interdisciplinary areas of trace and toxic element biochemical interaction, especially in regard to speciation. This latter subject is reviewed below in more detail.

In a recent treatise on ICPMS, Taylor et al. reviewed clinical applications of ICPMS. Clinical sample preparation is discussed and microwave digestion is highly recommended because the loss of volatile elements is minimized and contamination is under better control. Micronebulizers that operate with solution uptake rates of 85 µL min⁻¹ are particularly attractive since they are unaffected by viscosity and surface tension. While tissue analyses are preceded by a digestion step, biological fluids such as serum, blood and urine can be analyzed directly following dilution by factors of up to 50 or more to reduce the amount of matrix introduced into the nebulizer and, thence, into the skimmer cones. Detection limits that are comparable with ETAAS are made possible by the greater sensitivity of ICPMS.

Pruszkowski et al. presented a brief summary of clinical applications of ICPMS and discussed methods for correcting polyatomic interferences that can occur with those elements that are common constituents of biological matrices. For example, the determination of ⁷⁵As in urine is complicated by an interference from the ⁴⁰Ar⁴⁰Cl⁺ ion that also occurs at mass 75. An elemental correction equation is employed that subtracts the contribution from ⁴⁰Ar⁴⁰Cl⁺ by measuring its abundance at mass 77 (⁴⁰Ar⁷⁵Cl⁻), which must first be corrected for the ⁷⁷Se contribution. Several other polyatomic interferences exist for elements of clinical significance including ⁷⁷Al (CN⁻), ⁵⁲Cr (ArC⁻, OCl⁻), and ⁶⁵Cu (ArNa⁺). While use of correction equations may be necessary with ICPMS instruments equipped with quadrupole mass analyzers, use of instrumentation equipped with magnetic and/or electric sector mass analyzers, enable high-resolution inductively coupled plasma mass spectrometry (HRICPMS) to overcome many isobaric and polyatomic interferences.

Nixon and Moyer describe a simple method for the routine determination of four elements, Pb, As, Cd, and Tl, in human urine and whole blood using quadrupole ICPMS in the peak-hopping mode. Urine specimens are diluted by a factor of 10 with 1% nitric acid containing Ga, Rh and Bi as internal standards. Whole blood is treated in much the same way following centrifugation to remove cell debris. The interference for As at mass 75, caused by the ⁴⁰Ar⁴³Cl⁺ ion, is corrected by counting of ¹⁶O³⁵Cl⁻. Alimonti et al. determined Cr and Ni in human whole blood by ICPMS following microwave-assisted nitric-acid digestion. A Rh internal standard was used. The linear dynamic range was 0.03–30 µg L⁻¹ for Cr and 0.04–40 µg L⁻¹ for Ni in whole blood, with detection limits of 30 and 40 ng L⁻¹ respectively.

Paschal et al. used ICPMS to analyze a subset (n = 496) of urine specimens collected as part of the Third National Health and Nutrition Examination Survey (NHANES III) of the United States. Data for 13 elements (Mo, Pb, Sn, Tl, Sb, Mn, Cs, W, Pt, Ba, Be, Cr, Th and Co) were obtained at detection limits that surpassed what was previously possible with other techniques. Normal ranges for these analytes in human urine in the US population have now been established. Nuttal et al. describe their
experience with ICPMS for the routine determination of Al, Cu and Zn in serum, As, Cd, Pb, Mn, Hg and Te in whole blood, and up to 10 elements in urine. They report that Cr and Fe are particularly troublesome to measure in clinical samples by ICPMS because of polyatomic interferences.

In a recent review of trace element analysis of biological materials, Moens(144) described applications of mass spectrometry, including quadrupole ICPMS, HRICPMS, TIMS and gas chromatography/mass spectrometry. The advantages and disadvantages of inorganic mass spectrometry were compared with those of other spectroscopic techniques. Moens(144) believes ICPMS, as a successor to AAS and ICPAES, has some major weaknesses with biological materials, including matrix effects and mass spectral interferences by polyatomic species. Some workers(145) have used on-line anion-exchange columns to remove interferences from digested blood and urine samples prior to analysis by ICPMS. Using this approach, Ge, As and Se could be determined at detection limits of 70, 130 and 300 ng L⁻¹ respectively. Other workers have studied interferences from biological fluids, and have suggested use of RMs, and three internal standards rather than one in the determination of Br, Ca, Cr and Fe are particularly troublesome to measure.

According to Moens, however, although the multielement capability of ICPMS is one of its most advertised advantages, more than half of the papers published on biomedical applications deal with single-element determinations. Using a magnetic sector mass spectrometer coupled to a quadrupole ICPMS (i.e. HRICPMS), Moens et al.(144) reported the determination of V, Fe, Cu, Zn and Ag in human serum. Interferences from polyatomic species were significantly reduced with this HRICPMS compared with quadrupole ICPMS.

6.3.2 Single Element (Total) Determinations in Biological Materials by Inductively Coupled Plasma Mass Spectrometry

As with ICPAES methods, the most common single element (total) determinations in biological samples by ICPMS are those involving Pb, although methods featuring Al, As or Se are also reported.

Delves and Campbell(147) determined total and isotopic blood Pb concentrations by ICPMS with external calibration and matrix-matched standards. Blood samples were diluted 1 + 24 with the same solution they routinely use as a modifier with ETAAS methods: (NH₄)₂H₂EDTA, NH₄H₂PO₄ and Triton X-100, and which they reported does not block the Meinhard nebulizer. They report a within-run precision of 1.40% relative standard deviation (RSD) at 11.2 μg dL⁻¹, and a detection limit (3 SD) of 1.5 μg dL⁻¹. For Pb isotope ratio measurements, these authors report a between-run precision of 0.054% RSD for ²⁰⁶Pb : ²⁰⁷Pb and 1.02% RSD for ²⁰⁶Pb : ²⁰⁸Pb. Lead isotope ratios can be useful in apportioning the source of lead exposure in humans by characterizing the specific isotopic signature associated with different Pb sources. According to Delves and Campbell(147) the ²⁰⁶Pb : ²⁰⁷Pb ratio determined by ICPMS appears to give better discrimination between various exposure sources.

Paschal et al.(149) from the CDC used ICPMS in the ID mode to measure Pb concentrations in whole blood RMs. This approach gave values for blood Pb that agreed well with TIMS, and is currently used to establish certified target values for blood-based RMs in the CDC’s Blood Lead Laboratory Reference System (BLLRS).

Murphy and Paulsen,(150) from the US National Institute of Standards and Technology (NIST), independently described the application of IDICPMS to measure lead concentrations in NIST SRM 955a Lead in Blood. They achieved an overall precision on the order of 0.44% RSD around the 5 μg dL⁻¹ level (n = 10) and 0.22% around 12 μg dL⁻¹.

Bowins and McNutt(57) developed a procedure for the determination of Pb in plasma based on ETV/ICPMS with ID analysis. Because the majority (>95%) of Pb in whole blood is bound to the erythrocytes, normal concentrations of plasma lead are below the detection limit for most ETAAS methods. The mean value estimated by Bowins and McNutt is 1.27 μg L⁻¹ (6.1 nmol L⁻¹).

Brunk(151) described a simplified method for serum Al determinations by ICPMS. In this method, 500 μL serum is spiked with 500 μL Y internal standard, and diluted to 5 mL with water. The detection limit is given as 1 μg L⁻¹ and the limit of quantitation is 3 μg L⁻¹. Huang et al.(152) describe a FI hydride-generation method with ICPMS for determination of As in biological samples, including urine, with a reported detection limit of 0.6 pg. Rayman et al.(153) measured serum Se by coupling a hydride generation system to ICPMS. This arrangement produced a detection limit for Se of 0.04 μg L⁻¹, but the authors also reported a negative bias when analyzing selected RMs.

6.3.3 Speciation Analysis

In most clinical situations, only total element concentrations are routinely reported. This is because total element concentrations are relatively easy to determine, and are interpreted against an established clinical database of reference ranges. The analytical methods are well established and are under reasonably good control, and so the test results are considered reliable. However, reporting total element concentrations implies that only a single chemical species is present. Trace elements, and especially the transition metals, may not be present as a
single species. In respect of oxidation state, coordination number, stereochemistry and binding ligands, trace elements exist as many different chemical species, and with very different biochemical properties. One often cited example is the element Cr, which in the Cr(III) oxidation state is considered an essential element, but in the Cr(VI) oxidation state is carcinogenic. Perhaps a better illustration is the nonessential element Pt. Platinum is successfully used to treat several different tumors as the complex cisplatin (cis-diamminedichloroplatinum II). However, as the trans isomer, (trans-diamminedichloroplatinum II), it is highly toxic and shows no antitumor activity, despite having the same oxidation state and relative molecular mass as the cis isomer. Thus, an entire area of analytical chemistry has now opened up in which the determination of specific element species is the goal.

There are several excellent texts available that review the current status of clinical applications of speciation.35,36 Sanz-Medel36 describes the analytical strategies developed to tackle speciation problems in biological materials. They include computational approaches, direct species-specific systems and hybrid techniques. It is the latter where most efforts are now directed, and involve coupling a separation technique with an element-specific detector. With the emergence of ICPMS as a sensitive multielement detector, its potential in trace element speciation is immense. Most speciation methods focus on a single element, with determination of clinically significant species. They can range from a simple separation of organo-bound species from inorganic species to separation and identification of specific compounds. The separation step can involve the selective use of an on-line microwave-assisted heating arrangement to measure total element concentrations compared to just the inorganic species, or sophisticated chromatographic separations followed by element-specific detection. Most applications of the latter involve coupling the output from liquid chromatography (LC) systems to either AAS, ICPAES or ICPMS systems. Most LC arrangements utilize reversed-phase separations, many with ion-pairing, to separate metal ion species. Yet others have explored size-exclusion, capillary electrophoresis and other chromatographic approaches. Makarov and Szpunar154 review the use of size exclusion, or gel permeation, separations coupled with ICPMS for speciation in biological matrices. In an authoritative review, Cornelis35 discusses the current status of speciation studies for a wide range of elements: Al, As, Cd, Cr, Co, Cu, Hg, Ni, Pb, Pt, Se, Sn and Zn.

Several groups have succeeded in coupling element-specific techniques with chromatographic separation for the determination of selenium species in human body fluids. Yang and Jiang155 used ion-pair LC and ICPMS to measure selenite, SeO32−, selenate, SeO42− and trimethylselenonium (CH3)3SeO3− in human urine with detection limits of 0.76, 0.53 and 0.17 µg L−1, respectively. The LC eluant was fed into an ultrasonic nebulizer. Suzuki et al.156 used size-exclusion chromatography and ICPMS to determine Se-containing compounds in plasma, urine and RBC extracts from rats.

Element-specific techniques have also been coupled with separation techniques for the on-line determination of As species in serum and urine. Zhang et al.157 report using cation-exchange LC, UV photo-oxidation and continuous HGAAAS to determine monomethylarsonic acid (MMA), DMA, arsenobetaine (AsB) and arsenoxycholine (AsC) in human serum. Detection limits for the As species are 1–1.5 µg L−1. Serum from uremic patients was analyzed but only DMA and AsB were detected. The method was subsequently used to determine DMA and AsB in urine RMs.158 This same group also evaluated three type of LC systems coupled to HGAAAS to measure As species in human serum.159 The LC systems included reversed-phase ion-pair, and anion-exchange columns of both the cross-linked polymer and silica-bonded types. The latter appeared best suited to this kind of separation in serum samples, and inorganic As(III) and As(IV), MMA and DMA were determined with detection limits of 0.49, 0.44, 0.92 and 0.40 µg L−1 respectively. Ding et al.160 measured four Se species in urine using LC/ICPMS, including MMA, DMA, As(III) and As(V), with detection limits from 90–300 pg, and a dynamic range of three orders of magnitude.

Aizpun et al.161 described a method for the speciation of inorganic Hg0 and methylmercury (MeHg) in urine using LC and Hg detection by CVAAS. The linear dynamic range for MeHg was 10–400 µg L−1 and 16–400 µg L−1 for Hg0. Detection limits were 10 µg L−1 and 16 µg L−1 respectively. Yin et al.162 reported the determination of MeHg, ethylmercury (EtHg), phenylmercury (PhHg) and Hg0 in urine. Organomercury species are first preconcentrated on a C18 microcolumn, and then separated by reversed-phase LC with detection by CVAAS. Use of NaBH4 as a reductant combined with a thermolysis step improved sensitivity, and detection limits for MeHg, EtHg, PhHg and Hg(II) were 9, 6, 10 and 5 ng L, respectively, based on a 58.5 mL sample volume.

7 CLINICAL LABORATORY REGULATIONS

In the United States, all clinical laboratories that test specimens of human origin are regulated under The Clinical Laboratory Improvement Amendments of 1988 (CLIA 88), using a complexity-based model. The federal regulations that govern clinical laboratories are the responsibility of the Health Care and Financing
Administration (HCFA), which is an arm of the US Department of Health and Human Services (DHHS). The final rules implementing CLIA 88 were published in 1992. Other federal agencies also have responsibilities in clinical laboratory issues. For example, the Food and Drug Administration (FDA), which is also part of the DHHS, has responsibility for classifying clinical test devices marketed and sold in the US. The established analytical atomic spectrometric instrumentation that is typically used to determine elemental content in body tissues and fluids is classified as highly complex, which means such testing must be carried out in a duly licensed clinical laboratory facility. The Occupational Safety and Health Administration (OSHA), which is part of the US Department of Labor, issues regulations governing the biomonitoring of workers occupationally exposed to heavy metals. Clinical laboratories that test human blood or urine specimens for heavy metal exposure as part of an occupational monitoring program are required to be approved by OSHA too. In addition to federal agencies, many states also have laws governing clinical laboratory operations. Some states, e.g. New York, are “CLIA-exempt”, which means that any clinical laboratory based in that state, and holding a valid state permit, is deemed to have satisfied federal requirements, i.e. CLIA 88.

Clinical laboratory regulations cover a variety of matters ranging from the qualifications and education of the director and technical staff to the operation of the laboratory, its analytical methods, and the competency of the laboratory to perform those methods. QA and QC requirements are specified in the regulations. As part of the QA/QC requirements, all clinical laboratories must

participate in an external PT program that is approved by DHHS, and that reflects the specific laboratory specialty. For the trace element area, only blood lead is specifically identified for PT purposes under CLIA 88. Table 4 lists the currently approved PT programs for blood lead. The design of the PT program is specified under CLIA 88,\(^{163}\) Five PT challenges (or samples) are provided three times a year. Target values are established by the program, and the acceptable range for scoring results is fixed at \(\pm 4 \mu g \text{ dL}^{-1}\) or \(\pm 15\%\), whichever is greater. Sanctions may be imposed on laboratories that fail to report correct responses for at least 80% (four out of five) of the PT samples for two out of three consecutive test events.

Outside the USA, clinical laboratory standards vary considerably, and are beyond the scope of this text. The approach in Europe relies more on a voluntary compliance standard, with participation in EQAS encouraged. Several schemes are available that offer challenges for a range of trace elements in serum, blood and urine (Table 4).

8 QUALITY ASSURANCE AND QUALITY CONTROL

QA is defined as the planned and systematic activities implemented to provide confidence that an entity will fulfill requirements for quality.\(^{164}\) Within the analytical laboratory, QC is defined as a systematic process for evaluating and monitoring the accuracy and precision of any analytical process performed either repetitively in the same laboratory (internal quality control, IQC), or between laboratories (external quality control, EQC).\(^{164}\) Therefore, in a broad sense, components of a QA program will include staff training, standard operating procedure manuals, preventative maintenance programs, and documentation of remediation, as well as the more familiar aspects of QC that are part of the analytical phase, such as analyzing routine QC materials, that assure the accuracy and validity of the analytical result.

8.1 Reference Materials, Control Materials and Proficiency Testing

Weber\(^ {25}\) discussed laboratory quality within the context of environmental toxicology measurements. Although use of CRMs is recommended to verify accuracy, they are usually treated (e.g. lyophilized) for long-term conservation, and so may behave differently from real patient samples. Thus, the analyst should be cautious in interpreting CRM results. Weber concluded that participation in an intercomparison program, such as the Québec Trace Elements Intercomparison Program, is desirable to demonstrate that results are not only reproducible but also accurate. Taylor and Briggs\(^ {165}\) discussed changes that have occurred over a 10-year period in the Trace Elements EQAS that originated at the Robens Institute.\(^ {166}\) Assays assessed by the scheme now number 23, and include measurements in serum, whole blood, urine, dialysis fluids and water. Issues such as sample preparation, assay range, performance assessment and shared IQC programs are also discussed. They conclude that laboratory performance has improved considerably and cite as an example the measurement of Al in serum.

Since blood lead is specifically covered in regulations under CLIA 88, the situation here is much better. Three PT schemes for blood lead are approved by HCFA in the US (Table 4), and improvements in laboratory performance have been documented.\(^ {167,168}\) Elsewhere, laboratory improvements for blood lead have been documented as a result of participation in an EQAS.\(^ {169}\)

Reference materials are generally provided by government-run laboratories with expertise in the measurement of trace elements, and who provide a certificate stating the origin of the materials, the procedures by which values are certified and a statement of the analytical uncertainty. A listing of RM providers is given in Table 5. The NIST, formerly known as the National Bureau of Standards, has been particularly active in the development of well-characterized biological SRMs,\(^ {170,171}\) A listing of NIST's current clinical SRMs, with either certified or recommended values for trace elements, is provided in Table 5. Veillon et al.\(^ {172,173}\) described in great detail the procedures by which a bovine serum RM was prepared and characterized for up to 15 elements, which was later made available as NBS SRM 8419.

Control materials from commercial sources may be less well characterized, and “expected” values may not always be reliable, or they may be accompanied by very large uncertainties.\(^ {19,174}\) A listing of commercial control materials for trace elements studies in biological materials is given Table 6. Külpman et al.\(^ {63}\) analyzed NIST SRM 909 and several commercial control sera for Ca, Li and Mg using well-established FAAS reference methods, and compared the results with method-dependent target values. Their results confirm the reliability of FAAS as a reference method, but there was also considerable disagreement between expected Mg values and those actually found by FAAS. Parsons and Slavin\(^ {63}\) analyzed a number of commercial urine control materials for lead content using an ETAAS method that was validated with NIST SRM 2670, and New York State RMs for urinal lead. They found considerable variability with some commercial materials. Pizent and Teilsman\(^ {19}\) analyzed...

Commercial sera control materials for Cu and Zn using a FAAS method. Results obtained for three out of four controls were in good agreement but precision and accuracy for the other were poor. They suggest that nonhomogeneity of the lyophilized material and/or uncertified values were the cause. Veillon et al.\textsuperscript{175} analyzed a commercial control material for Cr, Zn and Se using IDMS and/or AAS. They found Cr and Zn were seriously affected by contamination from the sample containers. Other potential contaminants included B, Ba, Sr, Mo and Cu.

The use of well-characterized RMs for IQC has proven to be very successful in improving laboratory performance for blood lead.\textsuperscript{176} Delves\textsuperscript{177} argued that RMs, rather than reference methods, are more likely to improve laboratory performance, based on the experience

of European laboratories conducting blood Pb testing. Extrapolating from the blood Pb experience, it is likely that with the increased development of reliable clinical RMs certified for other trace elements, laboratory performance for other elements will improve too.\(^{(178)}\) This has certainly been the case for serum Al, which, like Pb, has been the focus of increased attention in recent times.\(^{(179,180)}\)

Clinical applications of analytical atomic spectrometry continue to appear in literature with even lower detection limits, improved performance and simpler sample preparation procedures. One area that has received attention recently is the development of low-cost, portable ETAAS instrumentation based on W-filament atomization, where measurements of Pb and Cd in blood have been shown.\(^{(181–184)}\) But as applications of ETAAS decline, ICPMS is emerging as a powerful alternative, and as the cost of ICPMS instrumentation becomes more affordable, more routine laboratories will likely adopt the technology. The limitations of current ICPMS technologies include isobaric and polyatomic interferences that originate from the sample matrix. In this respect, HRICPMS has some definite advantages but current instrumentation may be too costly for routine clinical laboratories. Development of atomic mass spectrometers that are more efficient at detecting atoms and use more of the sample will be required in the future. ICPMS instrumentation based on time-of-flight mass spectrometry will be a serious competitor to quadrupole-based systems. Perhaps the most interesting future developments will occur in speciation techniques, where information on specific metal species will become increasingly significant within a clinical context. However, there is still an urgent need for certified clinical RMs that contain endogenously bound trace elements certified at clinically relevant concentrations. Such materials will be needed to validate speciation methods.

Total laboratory automation (TLA) is an approach to laboratory instrumentation that replaces human operators with robotic devices for the performance of highly repetitive tasks in the preparation and transport of specimens. TLA will consolidate the control and oversight for multiple different analytical instruments to a smaller number of operators, thus reducing the costs of labor in laboratory testing. Benefits of TLA include reduction of human errors in specimen handling and improvements in overall process control, including faster turn-around-times (TAT) from specimen collection to test result reporting. Possible detriments include very high costs for equipment installation and disruption of workforces trained in existing technologies. Most clinical laboratories will soon face a decision about implementing TLA (or portions of it) to reduce operating costs in order to offset falling reimbursements for medical services.

1 INTRODUCTION

Clinical diagnostic laboratories are about to undergo a major change in which the performance of high-volume assays will be controlled completely automatically. The essence of this change is automation of several highly repetitive tasks that are now usually done manually in the preanalytical phase of processing specimens and presenting them to instruments. Other aspects of the new automation will include tracking and storing specimens so that they may be retrieved immediately for repeat (e.g. at dilution) or additional testing and ultimately discarded in a timely manner. The preanalytical tasks present immediate targets for automation; they include centrifugation, aliquot formation, transport to analyzers, and various judgments about specimen quantity and quality. The assays most likely to be involved include those for which automated analyzers already exist, such as clinical chemistry, hematology, coagulation, immunochemistry, and perhaps urinalysis. Highly repetitive tasks of preparing and presenting specimens for these analyses may be performed by robotic devices without direct intervention by human operators. Instead, the role of the operator should become one of monitoring quality control for a wide range of different assays simultaneously and to trouble-shoot problems that arise on instruments. A move toward such wide control over assays is actually an extension of manufacturing trends from the last few decades in which multiple assays have been installed on individual analytical instruments. Thus, linking multiple different instruments through a robotic processing and transport system completes the trend of multichannel analyzer development; the end result is termed “TLA”.

Implementation of TLA is expected to displace a large number of both highly skilled technologists and lesser skilled technicians, leading to disruption in the careers of many clinical laboratory scientists. Those who remain will either work in other disciplines that are not...
yet automated, or adapt to demands for new skills and competencies. The expected benefits from TLA include reduction in operating costs (primarily labor), reduction in errors, faster TAT and overall improvement in process control. The detriments of installing TLA are very high costs of acquisition and maintenance, displacement of workers, and the need to retrain employees to work in a new environment.

This presentation begins with a discussion of clinical laboratory processes and how their TATs affect delivery of healthcare. Emphasis is given to how these processes potentially can be controlled in a TLA laboratory. This presentation is organized from the viewpoint of a laboratory director who will make decisions about how and when to implement TLA based on progress in the industry and the critical need to cut operating expenses.

2 CLINICAL LABORATORY PROCESSES

The sequence of processes in the analysis of clinical laboratory specimens is traditionally divided into preanalytical, analytical, and postanalytical phases, each of which has multiple component activities (Figure 1). It is useful to include another earlier conceptual phase as well, because the requesting physician typically thinks of the entire process beginning when specific tests are first entertained to assist in diagnosis and medical management, even before test orders are formally placed. TATs are based on these individual phases; in practice, they are conveniently measured from the time that an order is entered into a hospital information system (HIS) or a laboratory information system (LIS) until the time when the results are verified and available to the physician through a computer. Time of receipt and acknowledgement of those results by the physician usually takes place at a later time that is not easily captured for calculating the total TAT.

2.1 Preanalytical Processes

In outpatient clinics, orders to collect specimens and perform specific tests are usually written on laboratory requisition forms by the requesting physician. Such orders are typically transcribed into a central computer of the medical center, which will assign unique specimen identification numbers, record specimen status as it reaches the laboratory, report test results to the physician, and keep those results in a file along with all other results on that patient for long-term information retrieval. Ordering of tests on hospitalized patients (inpatients) is typically done through direct entry into a computer system by the physician.

A work list of patients to be drawn by phlebotomists is generated by the computer system for scheduled (routine) and immediate (stat) collections from inpatients. Outpatients are generally handled individually in the order that they present in person to a phlebotomy station, thus obviating the need for comprehensive work lists in outpatient clinics.

Patient identification is accomplished by comparing the written order information with an inpatient’s identification bracelet and with active verbal responses that inpatients and outpatients make to standard questions about their identity asked by the phlebotomist. As trivial or mundane as this task may seem, it is crucially important because all subsequent activities rely completely on

---

**Figure 1** Components of activity in clinical laboratory processes.
Having accurately labeled specimens. There is no other failsafe mechanism to establish the identity of a specimen after it has left the patient's side; in fact, most so-called “laboratory errors” can be traced to mislabeled specimens, usually collected by nonlaboratory staff.

After positive patient identification, the specimen is collected. Blood samples are collected into standard vacuum tubes containing various anticoagulants to provide whole blood and plasma or clot-promoting powder and a separating gel to yield serum. Urine samples are generally collected into cups privately by the patient (except in medical–legal cases for drugs of abuse). Other body fluids (cerebrospinal fluid, peritoneal/ascites fluid, pleural fluid, joint fluid, gastric aspirate, etc.) are almost always collected by a physician working in a sterile field, but labeled by another person, sometimes not even at the collection site. Other specimens consist of wound swabs, sputum, skin scrapings, and other sources for microbiological culture.

The label should contain the patient’s name and identification number (e.g. medical record number, social security number, etc.). Initials of the person who collected the specimen and the time of collection are also handwritten on the label. More modern labeling consists of encrypting all this information into a bar-coded label generated by a central computer system. Ideally, the entire identification process could be done with portable bar code readers interfaced to the computer. The phlebotomist would identify and automatically record:

- the patient by scanning the bar code on the patient’s wrist identification band;
- the phlebotomist him/herself by scanning the bar code on an employee identification badge;
- the time of collection.

The label should be attached with the bar code parallel to the length of the tube (as opposed to being wrapped around the tube) for proper presentation to various bar code readers in subsequent steps.

Transportation of specimens to the laboratory is guided in part by the status of ordering. Stat specimens should be transported quickly (usually individually, as soon as they are collected); routine specimens may be held for batch transportation. Couriers can be used for both levels of these priorities; however, in a busy medical center the availability of couriers is not continuous and frequently is not sufficient for the need. Automated transportation systems are very useful for providing this service on demand around the clock. Such a system consists of pneumatic tubes (4–6 inches in diameter) that run between sending and receiving stations. Carriers fit flush within the tubes, allowing them to be propelled by air pressure from blowers. Complicated systems use switching stations as nodes to connect tens of stations within a building, and even extending to adjacent buildings up to a few thousand feet away. Transit times are usually 30–90 s or more; owing to acceleration and abrupt deceleration at switching nodes and upon landing at arrival, specimen integrity may be compromised and glass containers may break. Consequently, foam rubber padding and other protective wrap is needed. Pneumatic tube systems are controlled by their own computers, which can plan and track the course that a carrier follows; transit time from start to finish can be monitored for signs of system deterioration (e.g. air leak, increased resistance to movement, etc.) over long periods of time. One feature that is not incorporated yet into pneumatic systems is the identification of which specimens are transported in which particular carriers. Furthermore, emptying carriers is a manual task; some specimens may not be recognized by the human operator and so they are left in the carrier after it arrives in the laboratory. This lack of mechanical interface between pneumatic tube systems and analytical areas is a potential target for future automation.

Specimen accessioning is the process of confirming receipt of the correct specimen with label and test requisition in the laboratory. The activities usually include manual steps of matching specimen to requisition and entering data elements into an information system (either HIS or LIS) that uniquely identify that specimen for that patient. The next immediate step is to prepare the specimen for analysis. Whole-blood samples for hematological analysis (e.g. complete blood count (CBC)) are the simplest to prepare by inverting the closed collection tubes several times to mix the erythrocytes, leukocytes, and platelets thoroughly within the plasma. This preparation counters the settling of cellular elements that occurs when the sample sits in a fixed position. Most other common, high-volume specimens are intended for plasma or serum analysis; both are prepared by centrifugation. Plasma from blood collected into anticoagulants can be centrifuged as soon as the specimens are collected; common applications include the coagulation tests of prothrombin time (PT) and activated partial thromboplastin time (APTT) for samples collected into sodium citrate; also electrolytes and other chemical analytes such as glucose, urea, creatinine, etc. needed on a stat basis are collected into heparin.

Preparation of serum requires sufficient time for the blood to clot thoroughly prior to centrifugation. Usually the period from time of collection to receipt in the laboratory is sufficient for clotting to occur, unless the patient has been anticoagulated, in which case fibrin strands may continue to form in the supernatant after separation of serum from the clot. Fibrin strands from incompletely clotted serum can seriously interfere with the aspiration of a sample into analytical instruments,
which then may need to be cleaned before analyzing subsequent samples. This problem is usually prevented through visual inspection of all samples by an operator screening the specimens for problems. Collection tubes for serum samples commonly contain a separating gel that migrates to a position between the dense cellular clot and the lighter serum. These serum separator tubes help to preserve the integrity of many analytes in serum samples after centrifugation; when the serum is no longer in contact with cellular elements, constituents such as glucose, potassium, lactate dehydrogenase, etc. can remain stable for several hours while waiting analysis.

The original specimen tube may be placed directly onto an instrument for aspiration of the sample to analyze. Alternatively, an aliquot of serum is taken from the original draw tube and placed into a secondary tube that is placed onto the instrument; the secondary tube also must be labeled uniquely to identify it, usually with a bar code that is read by the instrument. When different types of tests are ordered on a single specimen, it is also common practice to use separate aliquots for analysis on different instruments.

Processed samples and their aliquots must be transported to the analytical instruments. Stat specimens may be carried individually as they arrive; specimens for routine testing may be taken to the instruments in batches arranged manually in test-tube racks or in analyzer-specific carousels for direct placement onto instruments. This transportation step is also one of the targets for automation of repetitive manual tasks.

### 2.2 Analytical Processes

Immediately prior to analysis, an operator typically judges the adequacy and quality of each specimen by visual inspection for volume, hemolysis, icterus, and lipemia. Specimens that are unacceptable or problematic for these reasons may be analyzed anyway, and the results reported along with a comment to let the physician interpret whether they are valid or not; or they may be tested by a different methodology that has less potential for interference. The latter alternative usually requires that a specimen be handled off-line along a nonautomated pathway. Sometimes this problem-searching step is done on an analyzer by measuring optical absorbance in the sample at wavelengths where hemoglobin and bilirubin have absorption maxima and where light scattering occurs.

Most modern laboratory equipment for high-volume testing has built-in mechanisms for aspirating samples from the specimen tubes placed onto an instrument’s carousel. Thus, once the instrument has been primed for operation, it automatically measures analytes in the specimen as directed through the instrument’s own computer. The desired tests may be entered manually into that computer by a technologist, or they may be transmitted directly from the LIS through an electronic interface to the instrument. The period of time over which a previously processed specimen resides at an instrument for sampling and analysis (i.e. instrument dwell time) can be as short as 30–90 s; test results then may be sent electronically from the instrument’s computer to the LIS.

Completed test results typically must pass some level of review before they are verified, at which point they are made available for reporting to the physician. The first criterion for accepting patient test results is whether quality control results are within acceptable limits using repeatedly analyzed sample material (usually commercially prepared). The general framework for accepting quality control results has been formalized by Westgard in terms of how many standard deviations away from the mean the present value lies and what the last several results were. In this manner, both abrupt changes in analytical performance can be detected as well as trends that may develop slowly. If quality control results are acceptable, then the entire batch of patient specimens can be assumed to have been tested while the instrument was functioning properly.

The second criterion for accepting patient results is sometimes called a “delta check”. In general terms, the delta check is a comparison of present results with previous results on the same patient. If analyte values have not changed by more than a defined percentage, then the specimen is judged to be from the correct (i.e. the same) patient, and the results are accepted for verification. These result review steps may be done by a human operator, or they may be done automatically by the LIS.

### 2.3 Postanalytical Processes

After verification, test results are immediately available to the ordering physician through the LIS or HIS if the physician has access to such a computer. Stat results are typically printed out by the computer at the patient’s location in a hospital ward or emergency room as soon as they are verified; stat results also may be reported by telephone to patient care locations not supported by computer. Routine results are reported by some slower mechanism, such as paper copy delivered by a courier the next day. One other category of results is panic or action values. These results are so abnormal that the patient may be in danger of dying from a chemical imbalance in a short time (e.g. very high or very low serum potassium; very high levels of therapeutic drugs that are toxic); the laboratory is responsible for recognizing panic values and reporting them directly to the physician immediately, whether the test was ordered stat or routine. Information systems play a major role in keeping track of these specimen priorities,
in following the appropriate reporting pathway, and in documenting reporting actions.

Specimen tubes are stored after testing for a few days to allow physicians to request additional tests or for repeat testing to confirm previous results. Specimens must be covered or recapped and then stored at refrigerated temperature. They should be stored in a sequential arrangement within each day’s specimens to allow timely retrieval when additional testing is requested. Specimens are stored for several days and then are discarded as biohazardous waste. Although these tasks of storage, retrieval, and discarding are simple actions in principle, large numbers of specimens can complicate the whole process enormously.

2.4 Turn-around-times

The “total TAT” is generally defined as the time from specimen collection (usually time of blood draw) to the time that test results are available through a computer system (Figure 2). This conventional definition of total TAT is commonly employed; however, physicians may perceive the TAT differently, namely from the time that the need for a diagnostic test is first considered on a particular patient until the physician actually receives a copy of the results in hand and can use them to make a medical management decision. The specific activities delineated in Figure 1 are conveniently denoted to belong to within-lab TAT, pre-lab time, or some other more distant actions perhaps relating to particular office or medical unit practice.

Clinical laboratories have greatest control of processes that occur within their own walls, and so naturally they can best monitor within-laboratory TATs. This period runs from receipt of the specimen at the laboratory with appropriate order through all processing and testing to the time that the result is electronically verified and is available on a computer system or is otherwise reported directly to a physician or medical team member (e.g. by telephone, facsimile transmission, paper copy sent by courier or pneumatic tube system, etc.).

Most laboratories promise within-lab TAT for stat tests of 60 min or less. Pre-lab time consists of collecting and transporting specimens to the laboratory; this time may be from several minutes to 30 min or more. Within-lab TAT for routinely requested tests may be 3–6 h for assays that are done throughout a 24 h day.

Many factors can influence the within-lab TAT:

- number and complexity of steps in accessioning and processing specimens (may be substantially different from laboratory to laboratory, frequently according to procedures dictated by an institution’s HIS, the laboratory LIS, interfaces between them, and how specimens are labeled);
- number of specimens arriving at the same time;
- number of resources (especially centrifuges and analytical instruments) available to handle the work load;
- number of personnel available to process specimens and perform testing;
- proportion of difficult specimens (e.g. small volumes collected from babies or geriatric patients; poor-quality specimens with hemolysis, icterus, lipemia, etc.) that require special handling;
- proportion of stat specimens (which require immediate attention) and routine specimens (which may be held for batch testing).

![Figure 2 Schematic of TATs for clinical laboratory processes.](image-url)
The goal of TLA is to develop new ways of performing these tasks in an effort to eliminate bottlenecks in the work flow of these within-lab activities. Other processes external to total TAT will not be altered directly by improving within-lab TAT. They may be improved more through use of better information systems and transportation devices that interface with laboratory automation systems (LASs).

As improvements in TAT occur, expectations for even faster TATs grow in the minds of physicians. Not only does faster performance by central laboratories fuel this expectation but so also does the growth of point-of-care testing (POCT), which can be done at the patient’s location with no requirement for transportation and essentially no waiting time for test results other than a brief period from sample collection to analytical completion. Many analytes such as glucose, coagulation times, arterial blood gases, and electrolytes can now be measured by POCT. It is expensive in terms of labor (one sample done at the time), reagent costs (generally prepackaged for single tests), and redundancy (many identical instruments sitting idle throughout a medical center). The challenge for future laboratory automation is to improve within-lab TAT so much, while keeping costs low and quality of results high, that centralized testing will remain preferable to distributed testing (POCT) in the minds of physicians who must rely on timeliness of results to treat their patients.

2.5 Likely Targets for Automation

Every place that a bottleneck now exists in clinical laboratory processes is a potential target for automation, especially if the tasks involved are highly repetitive and do not require a value judgment by a skilled operator. Within the laboratory, the possibilities include:

- **Accessioning** by optically scanning a bar-coded label that was placed on a specimen at the site of collection. This label may be sufficient for a specimen’s entire course through analysis and storage. Some laboratories now place a second label with bar code onto specimens after they arrive with another label (e.g. not bar coded, perhaps not specific for the specimen and requested tests, merely patient-specific with name and demographics). Double labeling is redundant, which makes it a clear target for improvement.

- **Centrifugation** of specimens to produce serum or plasma samples for analysis is generally done by an individual who inserts specimen tubes into holders and balances them in a centrifuge. After 5- to 10-min spins (according to specimen type), the operator removes the tubes manually for the next step in processing. The wait period between spins can vary considerably according to operator; furthermore, multiple specimens arriving at the same time may easily saturate the capacity of a centrifuge or the few that are assigned to processing. At the very least, automation of centrifugation can be expected to achieve uniformity in the timing of spins based on standard rules rather than on the arbitrary decisions of individual operators, who may have different approaches for waiting until a centrifuge is full or not before beginning a spin.

- **Aliquot formation** is done to allow a single specimen to be split for analysis on different instruments or even in different laboratory sections (e.g. chemistry and immunology). Different approaches to automation may change dramatically or even eliminate the need for aliquots. First, the specimen tube with bar code label from time of blood draw may be sampled directly, thus eliminating the need for an aliquot if only a single instrument is involved. Second, multiple smaller tubes may be collected from the patient, each for a different instrument. Third, a single large tube may be transported automatically from instrument to instrument for sampling without any aliquots. Fourth, aliquots may be made with a device that generates an additional bar-coded label for each aliquot tube to match the original label. Each of these strategies may be applied in different automation systems.

- **Transporting** specimens after processing to analyzers for sampling and analysis may be done automatically.

- **Storage** of specimens and retrieval for repeat testing or additional requests from a physician can both consume enormous effort (although probably few laboratories can define rigorously the actual work effort involved, due to extremely complex modes of storage according to date, time of analysis, which instrument was used, etc.). Each of these activities consists of repetitive tasks that are done manually in most laboratories but each potentially could be automated without loss of critical operator interactions.

3 CONTROL OF LABORATORY ANALYSES

It is essential for the laboratory to have information about what analyses to perform on which specimens. The path of this information begins with the ordering physician, who may fill out a paper requisition or enter test requests into a computer; this information provides direction for subsequent laboratory activities. The path culminates
Figure 3 Communication links between hospital and laboratory systems for transmission of information, from ordering laboratory tests to reporting results.

3.1 Laboratory Information Systems

The LIS provides the highest level of control for directing activities in a clinical laboratory. It receives orders for specific tests from the hospital information system (HIS; also called clinical system or medical information system). A modern HIS generally connects multiple functional units of a medical center, such as laboratory, pharmacy, radiology, dietary services, etc., with patient care units. Physicians, nurses, and other healthcare providers can gather medical information and request tests or treatments through a single HIS workstation, which in turn transmits those orders to separate information systems for laboratory, radiology, pharmacy, etc. The latest generation of clinical systems further integrates the HIS with all these other systems into a single system in which common databases can be shared readily, thereby facilitating searches and electronic manipulation of information. One common example is to confirm whether a patient is receiving anticoagulant medication (information stored in a pharmacy system) when coagulation test results are prolonged beyond the normal range (information in a laboratory system). Many other examples occur in therapeutic drug monitoring for antiarrhythmic, anticonvulsant, and antibiotic medications: what is the dosing schedule with regard to time of specimen collection for peak level, trough level, or other time of blood draw? Thus, the LIS acts as the main conduit of information from the HIS regarding laboratory requests. The LIS may also be the route by which requests are entered for specimens originating in locations not served by the HIS; this situation may arise with specimens collected at physician offices or other sites that use paper requisition forms for ordering.

All events that happen to specimens in the laboratory, beginning with accessioning, are either directed or monitored by the LIS. Of particular note is the role that the LIS plays in assigning accession numbers to each specimen that uniquely identify it versus thousands of other specimens potentially in the laboratory at the same time. The LIS can direct printing of specimen labels with bar codes to track each specimen as it passes through different sections of the laboratory and to identify each specimen as it arrives at an instrument for analysis.

Specific processing (e.g. centrifugation and aliquot formation) is dictated by the LIS, as well as the routing of samples for analysis to individual instruments. These particular tasks in theory may be under the moment-to-moment control of either the LIS or a LAS if it also has a computer that can receive orders from the LIS and then direct those activities.

The LIS is also interfaced to each analytical instrument for receipt of verified results after testing is complete. The LIS participates in verification through checks on quality-control sample results plus delta checks performed on individual patient results (see section 2.2). The electronic interfaces for exchange of specimen test orders and test results between LIS and instruments constitute a significant portion of set-up efforts and cost whenever a laboratory introduces a new automated instrument; not only are the laboratory and instrument vendor involved, but also the LIS vendor for programming and validation of information transfer. Some efforts have tried to link multiple instruments through a single interface engine to the LIS in order to keep costs lower; however, this concept must extend to include instruments from different manufacturers if it is to be successful and widely adopted.

The LIS should store test results in electronic patient files so that all results on a given patient may be retrieved together. This function allows the LIS to print result report forms for physicians to receive. Alternatively, reporting can be done by the HIS, or by a composite HIS/LIS in an integrated clinical system. Although result reporting occurs outside the formal walls of a laboratory,
it is practically the only way in which physicians can judge the performance and quality of laboratory services on a daily basis. Accordingly, laboratories place a great deal of effort in the function of reporting and communicating results to healthcare providers (e.g. panic values by telephone or paging system; printer or facsimile transmission to clinic office or medical ward sites). The reporting capabilities are just as important as analytical capacity whenever a laboratory is considering whether or not to accept new work; the cost of installing these additional peripheral devices becomes a factor in such decisions.

3.2 Laboratory Automation Systems

The LAS can accomplish several different tasks of specimen handling, processing, transport, presentation to analyzer, storage, and discarding. Such systems are modular, which allows the laboratory to choose particular functions for automation according to the most significant bottlenecks in the flow of specimen analysis.

TLA is a concept in which essentially all manual processes in the laboratory are replaced by automated systems. By TLA, no operator need handle or otherwise directly interact with patient specimens after they have been collected, transported to the laboratory, and placed into the receiving device for specimen handling. Of course, technologists or other operators would be needed to monitor quality control and system stability, as well as to trouble-shoot problems that arise unexpectedly with equipment or with particular specimens that may not be acceptable for automated analysis. Laboratory assays that are not automated, due to relatively low volumes or highly complex methods, would not be handled by TLA; however, the bulk of requests for laboratory work consists of a relatively small number of procedures that are performed widely on automated instruments that can be adapted readily to a TLA environment.

3.3 Processes in a Totally Automated Laboratory

In a totally automated laboratory, tubes of blood already uniquely identified with bar-coded labels are placed into some type of specimen carrier that will transport the specimen throughout the laboratory. Because tubes are recognized by bar code readers solely through their labels, all tubes from the same blood draw on a patient must have different accession numbers; by this means, tubes with different anticoagulants and clot tubes will not be confused with each other. Most automation systems read the bar code on the specimen label at various locations throughout the laboratory in order to track tube progress and arrival at workstations. Alternatively, the tube may be placed into a carrier that has a bar code label that becomes the unique identifier linked to the specimen tube during the period when the specimen is actively being processed and analyzed in the TLA system.

Reading the bar code (Figure 4a) may be facilitated by lifting and/or rotating the tube with a robotic device to move the label past an optical scanner. Picking up tubes, moving them in a prescribed manner, and placing them back into the carrier or other defined space are actions that require mechanical precision and accuracy plus gentle forces that will not damage glass or plastic tubes. Fortunately, much of the technology that is necessary for these manipulations has been developed already for other applications, such as the semiconductor manufacturing industry, and can be translated to laboratory medicine.

The carrier should allow several different things to be done with a specimen tube. First, it should be able to handle the different tube sizes that are common in medical centers treating widely different patients, some of whom cannot tolerate frequent draws of large tubes of blood (e.g. neonatal, pediatrics, geriatrics, oncology, etc.). The carrier must travel on a transport system between laboratory locations while holding the specimen in an upright position and keeping it from disruption. The carrier should hold the specimen firmly but allow the bar code label to be visualized through ports or openings to the side. If a specimen tube does break and potentially biohazardous blood or body fluid leaks out, the carrier should be cleaned and decontaminated readily for continued operation; it should also contain the spill as much as possible, to minimize its spread through the laboratory.

Once a specimen has been accessioned, it must be directed toward the appropriate preanalytical processing. Hematology samples are relatively simple in this regard because they can be sent immediately to a cell-counting instrument that analyzes whole-blood samples that are thoroughly mixed. As in the case of essentially all high-volume equipment, most clinical laboratories generally have two or more hematology analyzers; they provide back-up for one another during both planned and unplanned downtime for repairs and to do preventive maintenance; they also afford expanded capacity for testing during peak workload hours. The TLA system chooses which instrument should receive each specimen according to available instrument time, and delivers it to that workstation by way of a transport or track system.

Other specimens that are intended for chemistry, coagulation, and immunochemistry testing must be processed first by centrifugation. The TLA system recognizes these specimens by their bar code label and, using information from the LIS about requested tests, sends them to one or another centrifuge. The centrifuge is automatically loaded by a device such as a robotic arm, which places tubes into the centrifuge head with some action that also balances the centrifuge, such as putting other patient specimen tubes or blank tubes into opposite
Figure 4 Clinical laboratory tasks for which automation can replace repetitive manual actions.

positions (Figure 4c). After some defined waiting period (for additional specimen tubes to arrive and also be loaded), the centrifuge is spun for a prescribed time (usually 5 or 10 min). The robotic arm then automatically removes tubes from the centrifuge and places them into carriers for further transport.

One alternative at this point is to have the tubes placed into instrument-specific carousels that will be carried manually by an operator to the appropriate analyzer. This configuration uses automation solely for centrifugation, and so is formally not TLA; however, it accomplishes the goal of automating an early bottleneck in specimen processing that consists of repetitive tasks for which operator interaction and oversight add little to no value.

In a TLA configuration, following centrifugation, serum and plasma tubes are automatically decapped (Figure 4d) and the rubber stoppers are discarded. Sample volume may be estimated by a sensor that detects the top of the serum/plasma fluid level using infrared light, which can read through a label (Figure 4b). Alternatively, sample volume may be measured on analytical instruments by an aspirating probe that detects a pressure change at the airfluid interface at the top of the tube and another one at the serumgel interface in serum separator tubes.

Serum or plasma sample quality may be judged at this stage by examination for hemolysis (pink to red from hemoglobin in solution), icterus (intensely yellow
from increases in circulating bilirubin), and lipemia (turbid sample due to large amount of chylomicrons or occasionally other lipids), plus any other unusual appearance. These common specimen abnormalities cause a large number of potential interferences with assays that depend on optical absorbance measurements. One approach may be to ignore such specimen problems unless they cause marked abnormalities in test results, and only then examine samples for visual explanation of discrepant findings. Another approach is to station an operator at a viewpoint in the movement of tubes to observe the color and appearance of each sample; questionable ones could be identified and removed manually. Neither of these approaches is consistent with TLA because they depend on having an operator constantly available for interaction as part of the process.

To have a TLA system perform the specimen quality check automatically is not a trivial matter because of a technical problem: primary tubes may have at least two paper labels on them (one from the manufacturer and the second to identify the patient and specimen with a bar code), which will obscure the tube contents and block light from being transmitted consistently through the serum or plasma to detect absorption at wavelengths specific for hemoglobin and bilirubin, or scattering by particulate chylomicrons. Some analytical instrument manufacturers have already addressed the problem of detecting these interferences by aspirating the sample and making the appropriate optical absorbance measurements on the instrument itself. This capability could transfer the responsibility of interference checking from the TLA system to an instrument; however, a potential weakness may occur for samples that are intended for testing only on instruments that do not have the checking capability. In that case, it might still be possible to route the specimen to the checking instrument first for that function, even though that instrument will perform no other testing on it; the specimen then would be routed to the instrument for its requested tests, and the LIS would have the responsibility to track whether any detected interferences would be important for the assay procedures performed.

If aliquots are to be made for analyses on different instruments, serum or plasma is aspirated from the primary tube and dispensed into secondary (aliquot) tubes labeled with bar coding that relates them to the original specimen (Figure 4f). Using aliquots is not necessarily a preferred practice unless a laboratory has an extremely good reason to do so (e.g. a laboratory design in which only centrifugation and aliquot formation are automated; processed tubes are placed into separate specimen carousels for operators to place manually onto different types of instruments). If the processed specimen can be transported automatically to several different instruments in the same laboratory, that primary tube should be sampled directly by each of the instruments for which testing is requested. Avoiding the need for aliquots removes a step that consumes time, requires additional nonanalytical equipment, and increases the total number of tubes that must be dealt with in the whole TLA system at one time.

Transport to analytical instruments is done along a track system that runs horizontally above the floor. Motion along the track is referred to as the \( x \)-dimension (Figure 4e). Motion horizontally perpendicular to the track is in the \( y \)-dimension. Motion vertically perpendicular to the track is in the \( z \)-dimension. Transport between various workstations is essentially in the \( x \)-dimension (with whatever allowances are necessary for track curvature). When a specimen tube arrives in its carrier at an instrument, the instrument is set back in the \( y \)-dimension from the track. Because the TLA recognizes that the specimen tube has arrived at its proper testing site, the instrument may extend an arm with a probe in the \( y \)-dimension followed by descent into the tube along the \( z \)-dimension, to aspirate the sample (Figure 4g). This “direct track sampling” is done without moving the tube further. It can be accommodated by many instrument manufacturers whose protocol for sample aspiration consists of moving an arm with probe back and forth over a carousel of samples placed onto the instrument. Modification and extension of the arm motion readily allows sample aspiration to occur with the same devices but from a different direction (e.g. the back or side of the instrument past which the track runs). Another manner in which specimens may reach the instrument is for a robotic arm to lift the tube from its carrier on the track, place it onto the instrument for sampling by whatever method is involved, and return the specimen tube to its carrier for further transport.

Both the direct track sampling and tube-moving methods require that the tube be delivered by the track to the instrument in a defined position that is referred to as the “point of reference (POR)”. The TLA system has the responsibility to deliver the specimen tube to a target zone in which the instrument expects to find that tube. Communications and status reports are essential to achieve an orderly sequence of events in which the proper specimen is delivered to the correct instrument, a sample is aspirated, analysis is performed, and the specimen tube proceeds to other stations for further testing or for storage.

Once all tests are performed on a specimen tube, it is recapped (Figure 4h) and placed into a refrigerated chamber in a location from which it can be retrieved readily for repeat or additional testing (Figure 4i). In addition, the TLA should keep specimens organized so that when they are outdated they may be discarded in a timely manner.
3.4 Laboratory Workstations

One alternative to TLA is to use many of the same automated devices without using a track or other automated transport system. In this approach, automated centrifugation and other specimen processing would prepare tubes for operators to carry in batches to individual instruments for analysis. Following testing, the operator also removes the specimens and prepares them for storage. Although this configuration may appear to avoid the benefits of automation, it in fact maximizes the use of particular components for eliminating the traditional bottlenecks in which specimens entering the laboratory must await initial processing before they are taken to analytical instruments. Keeping operators involved also uses their judgment regarding specimen volumes and quality at a critical point before placing specimens onto analytical instruments.

4 WORKSTATIONS AND AUTOMATION

4.1 Trends in the Consolidation of Workstations

Over the last few decades, analytical instruments across many laboratory disciplines have followed similar lines of evolution. The first general trend has been to put more analyses onto a single analyzer. Chemistry instruments provide an excellent example: high-volume analyzers in most clinical laboratories now have the ability to perform a wide array of assays based on different principles of measurement, such as spectrophotometry and ion-selective electrodes. Essentially, all common serum and even urine analytes can be quantitated on the same instrument, thereby allowing a single technologist operator today to perform at a single workstation what 30 years ago might have required multiple operators manning ten or more different instruments. The labor component for generating these laboratory results thus has fallen markedly as multichannel analyzers have developed.

Other common trends in instrument development are related to the presentation of specimens. Virtually all analyzers now have the capability of reading bar code labels to identify specimens; they confirm specimen identity through electronic interfaces with the LIS, which also directs specific test performance and receives verified results through standard electrical parts. Random access mode of operation allows the analyzer to perform only those tests requested but at any time, so that batch mode is no longer necessary. Thus, multiple different assays can be done from a single sampling of a specimen. Sampling occurs by aspiration of serum with a disposable tip (to prevent carryover between specimens) on a probe that is moved into position by an instrument-controlled armature.

In hematology testing the CBC, with five-part differential, is now fully automated on a single instrument, with other features (such as reticulocyte count, immaturity markers for granulocytes and platelets, and lymphocyte surface markers) being introduced on the newest models. Automated immunochemistry analyzers also have made impressive gains, largely due to the easy availability of monoclonal antibodies as reagents for endocrine markers (thyroxine, cortisol), therapeutic drug monitoring markers (digoxin, other antiarrhythmics, anticonvulsants, antibodies), tumor markers (carcinoembryonic antigen, human chorionic gonadotropin, prostatic specific antigen), myocardial injury markers (myoglobin, creatine kinase MB, cardiac troponins I and T), and infectious disease markers (hepatitis viruses A, B, C). These immunoassays generally required 48 h for completion when they were introduced as radioimmunoassays many years ago; today they can be performed in minutes – a time frame that compares favorably with chemistry analyses. Accordingly, the next major consolidation is to link traditional chemistry analyses with immunoassays on the same instrument. This consolidation would potentially bring together two or three already large workstations into a single massive one. For a TLA environment, the consequence is greater simplicity for delivering specimen tubes to a single workstation for sampling into multiple channels of testing.

4.2 Characteristics of Instruments that can be Used in Total Laboratory Automation

Most high-volume instruments in use today have potential for incorporation into a TLA laboratory in which specimens are taken off a transport track or in which sampling occurs from a position with the specimen tube still on the track. How a particular instrument can be adapted to automated delivery of specimens depends to a great extent on how close the track can be mounted to the sampling device. In some instances, a vendor-supplied retrofit may allow sampling to occur from a side or rear location compared to normal front sampling. The task is made much more feasible when the instrument’s own armature and probe can be adjusted to move to virtually any site around the instrument, especially to the rear, where a track may fit flush against the instrument’s back.

The electromechanical interface between instrument and track system may be quite simple when it relies on readily modified instrument capabilities.

Current instrumentation in chemistry, immunochemistry, hematology, coagulation, and possibly urinalysis appears to be reasonably adaptable to TLA operations (Figure 5). Most of the limitations probably are related to software incompatibilities among instruments, LASs, and LISs rather than on mechanical incompatibilities. Other
long-term applications are likely to arise with automation of processes in laboratory sections that are presently highly manual, such as microbiology, blood banking, cytology, flow cytometry, and eventually perhaps histology and molecular diagnostics.

Of greater concern to the future success of TLA systems is the front end portion, namely the specimen processing devices that automatically load and balance a centrifuge and then unload specimens and produce aliquots in accurately labeled tubes. Few laboratories have had experience with these automated front ends, so little actually is known about their reliability. Because specimen processing begins the laboratory activities, it must be robust and immune from serious breakdown. Any downtime would require replacement with a duplicate system or extensive labor. Front-end processing entails high-speed moving elements, and so may have significant problems during an operational lifetime of several years on a 24-h day, 7-day per week basis.

5 ACCOMPLISHMENTS IN TOTAL LABORATORY AUTOMATION

The earliest efforts in TLA were implemented successfully in Japan, first by Professor Masahide Sasaki from the Kochi Medical School and then by companies such as A&T Corporation, Hitachi Instruments, Toshiba/IDS, and Sysmex Corporation. TLA systems have been implemented in many Japanese healthcare facilities. Because generally they have been interfaced with LISs that are not available in the USA, such TLA systems have not been directly transferable to other LISs in common use in North America. Accordingly, vendors are now making efforts for implementation in US laboratories with interfaces to different LISs. Current vendors of TLA systems or its components include Abbott Diagnostics (front-end automation and separate workcell automation at instruments), Auto Lab Systems, Bayer Diagnostics, Beckman Coulter, Inc., LAB-Interlink, Labotix, Roche Diagnostics/Boehringer Mannheim Corp., Sysmex Corporation (thermooptical absorbance; automated hematology system), and others possibly entering the market.

Because of the diversity of companies that may supply TLA systems and also of those manufacturing analytical instruments for clinical laboratories, the National Committee for Clinical Laboratory Standards (NCCLS), Wayne, PA has embarked on a program to set standards prospectively for developing TLA. The overall goal is to achieve standardization of equipment and processes so that instruments and automation systems will be highly compatible between manufacturers. This effort is intended to stimulate the overall growth of laboratory automation in the USA and elsewhere by encouraging standards that will minimize future problems of implementation at the individual laboratory level. As the culmination of this effort, the NCCLS has drafted five
standards that are currently or soon to be approved. They cover the topics:

- specimen container/specimen carrier;
- bar codes for specimen container identification;
- communications with automated clinical laboratory systems, instruments, devices, and information systems;
- systems operational requirements, characteristics, and information elements;
- electromechanical interfaces.

6 COST JUSTIFICATION OF LABORATORY AUTOMATION

The current financial climate is one in which reimbursement for laboratory and medical services in general has decreased and can be expected to decrease further. This reduction is true for all major classes of payers: private insurance; Medicare and Medicaid; indigent care (city, county, or state payments); and self-pay individuals. Managed care organizations negotiate low payment rates that are typically capitalized on the basis of covered lives and not the number of tests performed; doing more laboratory tests leads to no more reimbursement; doing less testing can be undesirable if it does not provide at least a minimum of preventive measures. Consequently, laboratories are generally expected to maintain productivity while reducing their costs of operation.

Capital expenditures are used to acquire large pieces of equipment and to make changes in building structures and utilities for installation. Acquisition of equipment for TLA is in this budget category; most institutions will depreciate capital purchases at a flat rate over a period such as 5 years. The source of capital may be private investors in a for-profit corporation, or it may be the excess of revenues over operating expenses (direct costs plus overhead and depreciation) in a nonprofit entity. In either case, the justification for major capital expenditure is usually a promise of reduced operating expenses (i.e. costs of labor, reagents, other consumables, and various purchased services such as maintenance contracts, etc.).

The evolution of workstations into consolidated multichannel analyzers has favored a reduction in labor expense because the number of personnel needed to operate fewer instruments has fallen. Technologists are utilized to prepare and present specimens to analyzers and to monitor quality control; they trouble-shoot when instrument problems arise. The current staffing pattern in most laboratories is one operator per instrument per shift. In a TLA environment in which robotic devices prepare and present specimens to analyzers, a single operator could monitor the quality control of several analyzers simultaneously and still be available for trouble-shooting. Thus, conversion to TLA has the potential to eliminate a substantial number of the workforce now employed in chemistry, hematology, immunochemistry, and coagulation testing. To justify the cost of implementing TLA or some of its components with a total price tag in the range of one to several million dollars would require staff reduction with total salaries over 5 years or less equaling the purchase expense. Some laboratories claim to have made such staffing reductions by implementing TLA; other laboratories have achieved similar staff reductions by reorganizing work flow without using TLA equipment. Consequently, the real challenge is for TLA to reduce staffing in an already pared-down laboratory. This issue is paramount today when laboratory directors consider the prospects for TLA.

How is a laboratory to assess its current performance versus other laboratories? Some form of benchmarking should be used to compare productivity (e.g. tests per technologist) and costs (e.g. total expenses per test) in similar institutions. One such program is the College of American Pathologists’ Laboratory Management Index Program (LMIP); using LMIP or another benchmarking system is essential for laboratories to assess whether improvements occur or not in response to changes that are instituted in operation. Reliable data regarding changes from TLA can be expected to appear in the next few years.

7 EXPECTED BENEFITS FROM TOTAL LABORATORY AUTOMATION

The major benefit expected to occur is a reduction or at least stabilization of labor costs by reducing the number of personnel involved in test performance. Financial benefit will be the major reason why institutions choose to invest in TLA. Other benefits also should be expected as a result of transferring repetitive tasks from humans (who are error prone in such work) to instruments and mechanical devices with extremely low failure rates. Thus, simple mistakes of labeling and specimen identification may be virtually eliminated by TLA as long as the patient is correctly identified at the time of specimen collection.

The whole process of specimen flow through a laboratory also should benefit from standard application of time sequences and decision rules for centrifugation, aliquot formation, analysis, storage, and retrieval/discarding of specimens. The within-laboratory time should improve with a high-capacity TLA system that can deliver specimens to instruments as rapidly as they can be analyzed. The distinction between stat and routine testing may also disappear as the throughput is optimized in a TLA laboratory.
One issue deserves special attention: what would be the consequences of making essentially all automated testing constantly available instead of batching some lower volume assays once per day (e.g. endocrine testing, therapeutic drug monitoring, hepatitis serologies)? Currently, most laboratories batch routine requests for these tests because the expense of reagents is high to perform quality control testing on each shift of operation when only a few patient specimens are analyzed. Thus, constant availability of testing could increase the fixed costs of an assay; however, these costs could be offset by lower labor costs associated with special handling for batched testing. The economics of this balance could be different for every laboratory and so must be resolved on an individual basis.

8 PROBLEMS AND DIFFICULTIES FROM TOTAL LABORATORY AUTOMATION

The overwhelming obstacle to initiating a course of TLA is the huge expense to acquire the equipment, although acquiring it gradually in stages may ameliorate the financial impact. Additional expertise at a high level will be needed to maintain TLA operations, although probably not substantially different from that already required for standard laboratory instruments. The interfaces between LAS and LIS as well as between instruments and LAS will be new to laboratories; they will require efforts to install and may be quite expensive beyond the initial costs of acquisition.

Probably the most daunting aspect of TLA will be the effect that it has on workers who are displaced. Unless they learn new skills, they may not adapt to a TLA environment. These changes will affect laboratory culture and the way in which people value themselves; institutions should maintain programs of essential continuing education to ease change and to bring out the best from workers as part of an overall strategy for implementing TLA.

9 FINAL ASSESSMENT OF TOTAL LABORATORY AUTOMATION

How can a laboratory decide whether it has done the right thing by implementing TLA? Improvement in laboratory processes from TLA should be assessed in terms of the following parameters: increased productivity per technologist; decreased cost per test; shorter TATs; fewer errors; and a better ability to monitor the flow of specimens through a laboratory. Although changes in intralaboratory processes probably will not be known to them, physicians should be satisfied with shortened TATs. Success in the reduction of TATs from TLA may be gauged in part by the reduction in the amount of decentralized testing performed as POCT for the same analytes delivered more efficiently and at less cost in a centralized laboratory. Finally, and very importantly, improvement should be judged also by employee satisfaction and the degree to which workers adapt to this new technology through re-education and commitment to changes that improve medical care.

The acute coronary syndromes (ACSs) are a continuum of myocardial ischemia ranging from angina, indicating reversible tissue damage, through frank myocardial infarction (MI) with extensive tissue necrosis. The mortality from acute MI in the USA alone is 500,000 deaths per year. New predictors of cardiovascular events, that are easily measurable, are needed to improve diagnostic strategies for treating ACS patients. Cardiac markers, proteins released from the injured myocardium into the circulation, are useful for the diagnosis of MI according to the World Health Organization (WHO) criteria. Troponins I and T have emerged as sensitive, more cardiac-specific clinical indicators for MI diagnosis and for risk stratification. A new generation of biochemical markers for indicating plaque rupture, platelet reactivity, and early MI offers promise for better assessment of patient risk so that clinicians may intervene to avoid adverse outcomes. Other biochemical markers, including the acute phase reactants and markers of thrombosis, may become useful for identifying a patient’s location on the ACS spectrum and consequently the risk of adverse events.

This article describes the spectrum of ACS current and future biomarkers that are closely linked to the progression of cardiac injury from ACS, and various applications of biochemical markers in assessment of reinfarction, reperfusion, perioperative MI, risk stratification, guiding therapeutic intervention, and infarct sizing. Finally, an assessment of the importance of rapid testing, different triage strategies for chest pain patients, and new trends to reduce the overall costs of patient hospitalization are discussed. The recommendations of the National Academy of Clinical Biochemistry for use of cardiac markers are also presented.

1 INTRODUCTION: WHERE DO BIOCHEMICAL MARKERS FIT IN?

The new advances in cardiology practice and the new knowledge in the pathophysiology of ACSs in addition
Utilization of biochemical markers of cardiac injury has evolved substantially over the past several decades. In the 1980s, cardiac markers were primarily used for diagnosis of MI. During the 1990s, it became clear that cardiac markers are elevated in cardiac ischemia patients who are at greatest risk of experiencing adverse events. Now at the start of the 21st century, it is reasonable to predict that cardiac markers will increasingly take on a new role for guidance of either medical and/or interventional therapy.

This article describes current and future markers for ACS and their applications in clinical setting for diagnosis of acute myocardial infarction (AMI), risk stratification, assessment of reperfusion, infarct sizing, and perioperative MI. Routine laboratory assays and point-of-care (POC) testing for the determination of cardiac markers are summarized. Finally, an assessment of the importance of rapid testing, different triage strategies for chest pain patients, and new trends to reduce overall cost of patient hospitalization are presented.

2 ACUTE CORONARY SYNDROMES: DEFINITION

For the past several decades, heart attack patients were largely regarded as having a binary condition, i.e. MI or non-MI, using the WHO recommendations that include at least two of the following three criteria: clinical symptoms suggestive of myocardial ischemia, characteristic changes on the electrocardiogram (ECG), and a rise and fall in serum biochemical markers. However, acute cardiac ischemia actually represents a spectrum of disease, termed the ACSs, which ranges from angina, reversible tissue injury → unstable angina, frequently associated with minor myocardial damage → MI and extensive tissue necrosis. The ACSs are a pathological continuum involving erosion and rupture of coronary artery plaques, activation of platelets, and typically mural or transmural thrombus. As indicated in Figure 1, the continuum of ACSs reflects the physiological process of acute myocardial ischemia and, most importantly from a clinical standpoint, a continuum of patient risk.

Much of the laboratory’s role has traditionally been associated with biochemical marker testing for diagnosis of ACSs, which ranges from angina, reversible tissue injury → unstable angina, frequently associated with minor myocardial damage → MI and extensive tissue necrosis. The ACSs are a pathological continuum involving erosion and rupture of coronary artery plaques, activation of platelets, and typically mural or transmural thrombus. As indicated in Figure 1, the continuum of ACSs reflects the physiological process of acute myocardial ischemia and, most importantly from a clinical standpoint, a continuum of patient risk.

of AMI, assessment of reinfarction or infarct extension, and estimating the quantity of infarcted tissue (infarct sizing). Logically, these roles have been clearly correlated with the WHO’s criteria for MI diagnosis. The laboratory’s future role will be more closely linked to the continuum of the ACSs through risk stratification and monitoring of thrombolytic therapy, platelet inhibition strategies, other therapeutic strategies, and perhaps interventions such as coronary angioplasty.

The events depicted in Figure 1 represent a spectrum of risk for an adverse outcome. Patients with stable angina, i.e. reversible ischemia, or myocardial preconditioning are at lower risk for adverse events in both the short-term and long-term compared with patients with Q-wave infarction. Identifying where an individual patient’s disease lies in the continuum of ACSs has biological implications regarding the reversibility of injury, quantity of ischemic cell injury, and the patient’s relative risk of an adverse outcome.

Much of the focus of biochemical markers has included markers of necrosis, the benchmark being creatine kinase (CK)-MB. However, other markers and substances shown in Table 1 are released or activated prior to necrosis and may have an important role in identifying risk in the ACS patient.

### 3 PATHOPHYSIOLOGY OF ACUTE CORONARY SYNDROMES

Rupture of atherosclerotic plaque occurs in 50–90% of patients with ACSs. The sequence of events in the ACSs includes plaque disruption, thrombus formation, abnormal vasomotion, platelet activation, and aggregation, as illustrated in Figure 2. Rupture of the surface of an atherosclerotic plaque in a focal segment of an epicardial coronary artery exposes thrombogenic components to circulation, which greatly increases the potential for thrombus at the site (Figure 2). Platelet aggregation and activation of the coagulation systems result in the formation of a platelet-rich thrombus (white
thrombus). A thrombus rich in fibrin and erythrocytes (red thrombus) may evolve and extend up- or downstream. Extensive local thrombosis will result in episodic flow-limiting coronary stenosis and myocardial ischemia associated symptomatically with unstable angina or with necrosis that characterizes non-Q-wave AMI. If the plaque rupture and thrombosis are extensive, the coronary artery could occlude completely and generally result in Q-wave AMI. In unstable angina patients, spontaneous ischemia results from reductions in coronary blood flow caused by atherosclerotic plaque combined with thrombosis and vasoconstriction. It is not clear, however, why disruption of a particular plaque would lead to occlusive thrombus in some cases but not others.

Circulating catecholamines have been shown to induce hypercoagulable state, vasoconstriction, platelet activation, and thrombin generation. Therefore, states of sympathetic nervous system hyperactivity such as emotional stress, smoking, and extensive exercise may contribute to arterial thrombosis formation. High cholesterol levels are associated with hypercoagulability and platelet hyperactivity at the site of experimentally induced acute vascular injury. Finally, diabetes mellitus may increase platelet reactivity and induce coagulation. Diabetics who are not treated intensively have a significantly higher incidence of MI. Infectious diseases may also play a role (see section 5).

4 DIAGNOSIS OF MYOCARDIAL INFARCTION

Careful assessment of clinical symptoms is of paramount importance, but can be nonspecific in up to one-third of patients, particularly in diabetics and the elderly who most frequently present with atypical symptoms of ischemia. ECG monitoring is also an important tool that should be performed quickly after presentation of the suspected MI patient because those having diagnostic changes are candidates for immediate reperfusion therapy. The electrocardiograph, however, is not a perfect instrument because its clinical sensitivity for MI is only about 50%. The third WHO criterion, monitoring a rise and fall in cardiac markers, is considered the benchmark for the diagnosis of MI. In symptomatic patients presenting with diagnostic ECG changes, biochemical markers have a limited role for acute MI diagnosis, except for confirmation. On the other hand, biochemical markers are essential for assessment of patients who present with nonspecific or vague symptoms and a nondiagnostic ECG. These nondiagnostic ECG patients comprise the majority, about 55%, of individuals eventually diagnosed as having MI. It is of note that in 4–8% of MI patients the diagnosis is missed, and there is high mortality among this group. Further, misdiagnosis of MI represents the highest outlay of malpractice costs among Emergency Medicine physicians. To help deal with this high prevalence disease and its substantial associated costs, many institutions have initiated a Chest Pain Evaluation Center (CPEC), a specific protocol-driven treatment area intended for systematic and cost-effective care. Rapid, real-time availability of cardiac markers has become an integral part of most CPEC protocols. Recent research has shown that the rate of missed MI was cut from 4.2% to 0.4% by establishment of CPEC protocols.

5 LINK BETWEEN HEART DISEASE AND INFECTIOUS DISEASES

The potential link between infectious diseases, such as typhoid, scarlet fever, and sepsis, and atherosclerosis dates back to the late 1800s. In the 1940s, researchers noted a strong association between atherosclerosis and a herpes-type DNA virus known to cause T cell lymphomatosis. Other diseases linked to infections include peptic ulcers caused by Helicobacter pylori, kaposi’s sarcoma caused by herpes simplex virus, and the association of hepatocellular carcinoma with hepatitis B virus. There has been substantial research investigating the association of heart disease with Chlamydia, an obligate intracellular bacterial pathogen of eukaryotic cells. Using immunocytchemistry, polymerase chain reaction, and culture techniques, several reports have demonstrated that C. pneumoniae can localize to blood vessels. Other research groups found Chlamydia proteins in 79% of plaque specimens obtained from the coronary arteries of heart disease patients, versus only 4% of heart artery walls of normal individuals. Infecting rabbits with Chlamydia measurably thickened the arterial walls of...
the animals, especially those fed high-fat diets. Treatment of infected animals with azithromycin, an antibiotic used to treat Chlamydia infection, resulted in normal arteries that appeared similar to those of uninfected animals.

Mechanistically, molecular mimicry may play a role. A peptide from the murine cardiac specific α myosin heavy chain with sequence homology to a cysteine-rich outer membrane protein of Chlamydia pneumoniae, C. psittaci, and C. trachomatis was demonstrated to induce autoimmune inflammatory heart disease in mice. Injecting the homologous Chlamydia peptides into mice was also shown to induce perivascular inflammation, fibrotic changes, and blood vessel occlusion in the heart, in addition to triggering T and B cell immune responses to the changes, and blood vessel occlusion in the heart, in addition to triggering T and B cell immune responses to the changes.

Chlamydia DNA functions as an immune booster "adjuvant" in the triggering of peptide-induced inflammatory heart disease. Infection with C. trachomatis led to the production of autoantibodies to heart muscle-specific epitopes. Therefore, it is suggested that Chlamydia-induced heart disease is mediated by antigenic mimicry of a heart muscle-specific protein. In other studies, introducing live bacteria by catheter and syringes into mice caused heart inflammation. It is important to note, however, that the inflammation resulting from the mimicry seems confined to the heart muscle rather than extending to the arteries where it could trigger atherosclerotic plaques. One theory postulates an "echo effect" which may explain how microbes affect arteries that are some distance from the primary infection sites.

Many questions remain regarding the potential etiological role of infections in the formation and development of atherosclerosis. It is not clear whether bacteria are direct contributors to atherogenesis or simply innocent bystanders. Would antibacterial therapy be useful for the prevention and treatment of arterial disease? If so, may vaccination be an option for ultimate prevention? Clinical studies are necessary to clarify issues concerning infectious causes of atherosclerosis.

## 6 METHODS FOR CARDIAC MARKER MEASUREMENTS

### 6.1 Electrophoresis

Electrophoresis refers to the migration of charged particles in a liquid medium under the influence of an electrical field. Electrophoresis on agarose or cellulose acetate can separate the CK and lactate dehydrogenase (LD) isoenzymes. The isoenzyme bands can be visualized by incubating the support with a coupled reaction and the resulting nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH) can be detected by observing fluorescence following excitation by long-wave (340 nm) ultraviolet (UV) light or by reacting the NADPH formed with a tetrazolium salt to form a colored formazan. Electrophoresis is usually considered a labor-intensive and time-consuming technique.

### 6.2 Immunoassay

#### 6.2.1 Immunoinhibition

In this technique, anti-CK-M sera inhibit both M subunits of CK-MM and the single M subunit of CK-MB, allowing the determination of enzyme activity of the B subunit of CK-MB. A caveat with this method is that B subunits of CK-BB, any macro or mitochondrial CK activity, or adenylate kinase (AK) may interfere. However, when CK-BB is present in a specimen, its activity is <5 U L⁻¹, which is below the detection limit of the immunoinhibition technique. However, other sources of interference may also give false-positive CK-MB results.

#### 6.2.2 Two-site "Sandwich" Immunoassays

In contrast to immunoinhibition and electrophoresis techniques, which measure the isoenzyme by determination of enzyme activity, immunoassays measure the enzyme as a protein. Immunoassays for enzymes, e.g. CK-MB, are termed mass assays. "Mass" assays have no dependence on whether or not the enzyme is catalytically active. Several sandwich immunoassays are currently available for myoglobin, CK-MB, cTnI and cTnT.

### 6.3 Point-of-care Testing

The fundamental driver of POC testing is that caregivers in triage, treatment, and patient monitoring areas base time-sensitive decisions on the results. Cardiac marker testing has evolved from labor-intensive, rather esoteric assays, that were offered once per day, to systems with a turnaround as fast as 10–15 min once the front-end work of transport, centrifugation, serum–plasma separation, and instrument set-up is completed. The practice of batching these assays, even multiple times per day, may become an anachronism. POC testing may be defined as assays that are performed either directly on the patient, at the bedside, or at "near-patient" satellite locations. POC testing of myocardial injury markers may evolve into a standard of care for workup of acute cardiac ischemia. Table 2 lists criteria for POC testing of cardiac markers.
Table 2 Criteria for POC testing of cardiac markers

| A strategy for specimen collection and transfer that minimizes risk of infectious disease |
| Rapid TAT |
| Low volume, preferably whole-blood sample |
| Direct application of a noncritical volume or placement of sample directly into instrument |
| Disposable device or minimal maintenance required |
| Minimal technical expertise required |
| Positive identification and specimen tracking strategy that eliminates specimen identification errors |
| Simple strategy for recording collection time and result reporting |
| Simple strategy for calibration and quality control |
| Transferability of data to the Laboratory Information System and/or Hospital Information System |
| Agreement of results with accepted “gold standard” assays |

Affordable cost

6.3.1 Trends and Limitations for Point-of-care Testing of Cardiac Markers

There is a clear need for better defined strategies that integrate ECG, clinical symptoms, biochemical markers, and other technologies for care of cardiac patients. A model for achieving this integration has been implemented in many institutions through the establishment of areas that focus on care of patients suspected of having acute cardiac ischemia. The National Heart Attack Alert Program (NHAAP), an initiative of the National Institutes of Health (NIH) National Heart Lung and Blood Institute, has recently published document No. 93-3278, which endorses the rapid identification and treatment of AMI patients in emergency department (ED) areas, such as CPECs. The role of POC cardiac marker testing must be evidence-based; real-time or POC testing for cardiac markers may not be appropriate for all aspects of care in the context of cardiac ischemia. Specifically, clinical and economic considerations may never warrant POC testing for the initial assessment of ACSs in patients for whom ECG changes are diagnostic of myocardial necrosis. POC testing may be important for noninvasive assessment of reperfusion and for guidance of therapy because TAT is vital if therapy has not been successful, and alternative patient care strategies must be considered in the early phase to “open the artery”. POC measurement of biochemical markers may also be helpful for assessing infarct artery reoclusion and reinfarction.

7 DECISION LIMITS FOR MARKERS

In the context of cardiac markers or other chemical laboratory tests, interpretation consists of comparison with previous knowledge, ideally from studies conducted in an identical population. These data are best collected through a prospective cohort study design in which the reference standard is applied to every patient, and the results are examined in a blinded fashion. The size and characteristics of population studied, enrollment criteria, and clinical setting in which the studies are conducted should reflect closely the practice environment in which the test will be used. The data must then be analyzed using appropriate mathematical techniques. These techniques and their application in the context of biochemical markers have been reviewed recently.

Calculations of clinical sensitivity, specificity, and predictive values have been the traditional means for assessing the efficacy of tests, although it is important to note that other more effective strategies are available. Clinical sensitivity, specificity, and predictive value calculations require that the outcome be expressed in binary terms as positive, i.e. indicating the presence of a specific outcome, or negative, indicating the absence of the outcome. Analysis of test performance requires designation of decision limits or “cutoffs” for examining whether the test data accurately reflect the patient’s positive or negative condition. Thus, test results are classified as either true positive (TP), where the test is above the decision limit and the patient has the outcome; true negative (TN), where the test is below the decision limit and the patient does not have the outcome; false positive (FP), where the test is positive but the patient does not have the outcome; or false negative (FN), where the test is below the cutoff but the patient has the outcome. Calculations for clinical sensitivity, specificity, and positive and negative predictive values (NPV) are based on the following:

- sensitivity = TP/(TP + FN)
- specificity = TN/(TN + FP)
- positive predictive value (PPV) = TP/(TP + FP)
- NPV = TN/(TN + FN).

An important issue is that PPV and NPV are dependent on the prevalence of the specific positive outcome in the population tested.

Various methods for deriving cutoffs have been used, including use of the assay’s minimum detectable concentration or the 97.5 percentile for either healthy individuals or “rule-out” patients. These cutoffs, however, are usually inappropriate because they do not consider performance of the test in the positive outcome population. Receiver operator characteristic (ROC) curves, logistic regression analysis, neural networks, and calculation of likelihood ratios are all better evaluation techniques for comparing a patient result to the previous knowledge.

For the construction of ROC curves, data are typically displayed for the outcome groups. The data are examined
at a continuum of different cutoffs, with determination of the TP, FP, TN and FN results at each; these results are used to calculate clinical sensitivity and specificity at each individual decision limit. The ROC curve is constructed by plotting sensitivity on the y-axis and (1 − specificity) on the x-axis. The ideal test has an area under the ROC curve of unity.

ROC curves are an effective means for both determining decision limits and for assessing the relative accuracy of tests. The upper left corner of the ROC curve indicates the minimum tradeoff of FP and FN results; this point is frequently considered the optimum decision point. It is important to note when examining cutoffs with ROC curves that there are often insufficient data in the area of the optimum cut off to provide a high degree of certainty.

ROC curves can also be used for comparing two or more tests examined in the same population. Areas under the ROC curves for each test can be calculated and compared for differences to show if one test is better than another for diagnostic performance.

8 SPECIFIC MARKERS OF ACUTE CORONARY SYNDROMES

8.1 Characteristics of an Ideal Cardiac Marker

The ideal marker would have absolute cardiac specificity to allow reliable diagnosis of myocardial injury in the presence of skeletal muscle injury. An ideal marker should not exist in other tissues under normal or pathological conditions. It must have high diagnostic sensitivity; the marker should be enriched in cardiomyocytes to indicate even minor damage such as in unstable angina and myocarditis. It should be able to differentiate between reversible (ischemia) and irreversible (necrosis) damage. In AMI, the marker should permit monitoring of reperfusion therapy and the estimation of infarct size and prognosis and should allow both early and late diagnosis. The marker should be stable and appear in blood immediately following damage, but remain in circulation long enough to allow detection then be eliminated from circulation to allow detection of reinfarction. A rapid (whole blood is desirable), easy to perform, quantitative, and cost-effective assay should be available for this marker. It is important to note that no such marker is known at present. Finding a single marker with all these characteristics could be impossible, so the use of a panel of markers may be necessary.

8.2 Myoglobin

Myoglobin (17 800 Da) is a heme protein that is located in the cytoplasm of both cardiac and skeletal muscle cells. As shown in Figure 3, myoglobin is among the earliest appearing biochemical markers routinely available for assessment of the ACS after myocardial damage. Myoglobin’s characteristic early rise and rapid clearance are mainly due to its relatively small molecular size, high concentration in tissue, and renal clearance mechanism. Because myoglobin’s amino acid sequence is the same in both cardiac and skeletal muscle, this marker has decreased clinical specificity due to positive results in populations having skeletal muscle injury. Also, patients will have elevated myoglobin levels due to decreased clearance from blood. Myoglobin elevation in noncardiac disease indicates why the clinical specificity of this marker depends on the population tested. The clinical sensitivity of myoglobin is accepted to exceed 90–95% within 6 h of presentation. The role for myoglobin in testing guidelines focuses on early clinical sensitivity, with rapid availability of results. As indicated in Table 3, there are a number of studies that have examined the NPV of myoglobin, finding satisfactory high values when chest pain onset is acute. Based on these data, testing strategies at many medical centers include myoglobin, in combination with more myocardial specific markers, because of its high NPV. On the other hand, many institutions believe that myoglobin adds very little information, and in fact the NHAAP report referred to above rated the clinical impact of myoglobin as “+”, indicating only modest accuracy and small clinical impact.

In summary, myoglobin has high NPV in the early hours after MI. Serial sampling with optimum timing at presentation and between 2 and 6 h later is necessary to optimize clinical utilization. Not all clinicians are convinced that myoglobin measurements contribute significantly to the assessment of ACS patients. To be useful, myoglobin
Table 3 Various studies that have examined the NPV of myoglobin measurements: a total of 972 patients were included in these studies, 218 (22.4%) being diagnosed as having MI

<table>
<thead>
<tr>
<th>Study</th>
<th>No. of patients (MI)</th>
<th>NPV (%)</th>
</tr>
</thead>
</table>

Results must be available in real time, i.e. with an available testing TAT of approximately 0.5–1 h, in a time frame useful for decisions in the early assessment of patients. The major method used for myoglobin measurement is two-site immunoassay.

8.3 Creatine Kinase-MB Isoenzyme

CK (85 000 Da) is an enzyme located in the cytoplasm of all striated muscle cells where it catalyzes the phosphorylation of creatine to creatine phosphate. Cytoplasmic CK is dimeric, composed of M and/or B subunits that associate to form CK-MM (CK-3), CK-MB (CK-2), and CK-BB (CK-1) isoenzymes. At present, CK-MB is an important tool in the evaluation of ACSs because it has been established as a benchmark for biochemical markers of MI due to experience spanning more than two decades. In patients having significant myocardial disease, the CK-MB isoenzyme comprises approximately 20% of the total CK in this tissue. CK-MB is diagnostically sensitive for myocardial injury, but skeletal muscle has both higher total CK activity per gram of tissue and may be comprised of up to 3% CK-MB. This potentiates compromised diagnostic specificity, particularly in patients with concomitant myocardial and skeletal muscle injury. To confer greater cardiac specificity to CK-MB measurements, a CK-MB “index” is frequently calculated according to

\[
\text{Equation (1)}: \quad \text{CK-MB index} = \frac{\text{CK-MB}}{\text{CK-total}} \times 100\% \quad (1)
\]

Some authors suggest that CK-MB index values exceeding 2.5% are associated with a myocardial source of the MB isoenzyme; however, a recent review shows that the index is reportedly as low as 2% and as high as 5% depending on the variability of both the numerator and denominator.

As indicated in Figure 3, the first rise in CK-MB after MI requires 4–6 h after onset of symptoms, but serial sampling over a period of 8–12 h is required for diagnosis with high diagnostic sensitivity and specificity. CK-MB mass assays were examined in a meta-analysis for the retrospective diagnosis of MI within 12–48 h after onset of symptoms or admission. This analysis showed that CK-MB had a clinical sensitivity of 96.8% [95% confidence interval (CI) = 95–98%] and a clinical specificity of 89.6% (CI 87–92%). Also, the NHAAP evaluated cardiac marker utilization focusing on the ED environment. When used with multiple sampling, CK-MB testing was very accurate for the diagnosis of MI and was noted to have a large clinical impact. Despite this excellent clinical performance, CK-MB is not an ideal marker because its rise requires 8–12 h after symptom onset for use in diagnosis and tissue specificity is an issue. Methods for CK-MB measurement include electrophoresis, immunoinhibition, and so-called “mass”
assays, which are two-site immunoassays. Most of the mass assays utilize the Conan antibody developed at the University of Washington, St. Louis, MO, USA. Specific determinations of CK-MB require the application of the “sandwich” technique in which two antibodies (anti-M subunit, anti-B subunit, or anti-MB) with affinities for different epitopes of the CK-MB molecule are used sequentially. The first antibody (usually a monoclonal) is immobilized on a matrix, while the other antibody is conjugated with a label reporter molecule. CK-MB mass assays are automated, highly sensitive (\(<1 \mu g L^{-1}\)), and specific, and have a rapid TAT (as short as 7 min), giving them characteristics that surpass other technologies for measurement. A number of mass assays, using various labels, are commercially available and used for routine and emergency measurement of CK-MB. These methods require the use of CK-MB calibrator standards, and there are no agreed-on values or materials. Recently, the American Association for Clinical Chemistry proposed CK-MB2/CK-MB1 ratio becomes abnormal (\(>\)1.5) before CK-MB levels rise above normal. Studies have shown diagnostic sensitivities of up to 92% for detecting AMI at 4–6 h. In unstable angina patients, CK-MB isoforms were increased in 29.5%, myoglobin in 23.7%, troponin I (TnI) in 19.7%, and troponin T (TnT) in 14.8%. For early diagnosis of MI, CK-MB isoforms and myoglobin were concluded to have the best sensitivity.

Helena Laboratories (Beaumont, TX, USA) have developed an automated Cardio REP system to quantify CK isoforms. This system can assay six specimens within ~18 min. This rapid TAT is achieved by automation of pipetting, electrophoresis, substrate spreading, and incubation, gel drying, and the use of high-voltage electrophoresis and computer-controlled densitometry. CK-MB isoforms migrate anodic to those of CK-MM; CK-MB1 is the fastest moving, most anodic band of the MB series.

8.5 Lactate Dehydrogenase

LD, an important enzyme of glucose metabolism, exists as a tetramer of approximately 135 kDa. Mammals have two different types of subunits, M and H, which together form five isoenzymes, H4, MH3, M2H2, M3H, and M4. According to their electrophoretic mobility (from anode to cathode), these isoenzymes are referred to as LD1, LD2, LD3, LD4 and LD5, respectively. In the aerobic heart tissue, the H4 tetramer predominates, but the M4 isoenzyme predominates in skeletal muscle. LD exists in almost every tissue and is abundant in skeletal muscle, heart, brain, kidneys, lungs, and erythrocytes. LD isoenzymes differ in their stability: LD4 and LD5 are unstable at temperatures > 45°C or at −20°C, whereas LD1 is stable up to 65°C. Electrophoresis followed by densitometry is the method of choice for the separation of LD isoenzymes and the detection of LD1–LD2 flip in AMI. Following onset of chest pain, LD activity starts to rise by 8–12 h, peaks at 24–72 h, and returns to the baseline by 8–14 days. Normally LD1 does not exceed 40% of total LD activity. Following myocardial damage, however, LD1 activity exceeds LD2 activity, and the LD1/LD2 ratio is fairly specific for myocardial injury. Determination of LD isoenzyme adds little to the diagnosis of AMI if elevated CK-MB levels have already been detected. Similarly, LD isoenzymes that have low tissue specificity are no longer the marker of choice for detection of late-presenting MI, because other cardio-specific markers such as troponins that have long half-lives in blood are better suited for this purpose.

LD1 has been used to assess infarct size in AMI patients by calculating the cumulative enzyme release. A decrease of the enzyme activity that corresponds to a reduction of infarct size after thrombolysis was observed in patients with ST elevation in the initial ECG. (ST segment is a component of the ECG complex.)
LD1 is enriched in erythrocytes, free hemoglobin levels can be used to correct for LD1 activities contributed by erythrocytes.

Immunoinhibition methods and electrophoresis followed by densitometry have been used for the separation of LD isoenzymes and the detection of LD1–LD2 flip in AMI patients. With the wide availability of troponin assays, LD measurements for MI diagnosis are considered an anachronism.

### 8.6 Proteins of the Troponin Complex

The troponin complex is located on the thin filament of the contractile apparatus in striated muscle and consists of three subunits: TnT, which binds to tropomyosin; troponin C (TnC), which is the calcium-binding subunit; and TnI, which binds to actin. Specific isoforms of TnT and TnI are found in both cardiac and skeletal muscle. The isoforms found in cardiac muscle (cTnT and cTnI) are encoded by different genes to those found in skeletal muscle, resulting in slightly different amino acid sequences between the two forms. This makes it possible to produce antibodies that are specific for only the cardiac forms. Because TnC has identical amino acid sequence in both skeletal and cardiac tissues, it has little potential as a cardiac marker.

TnI (23,500 Da) is the inhibitor of the troponin–tropomyosin regulatory complex that confers calcium sensitivity to actomyosin adenosine triphosphatase (ATPase) activity in striated muscle, thus modulating the interaction of actin and myosin in these muscles. cTnI has a unique amino acid sequence that shows 40% dissimilarity from the two skeletal muscle isoforms (slow-twitch and fast-twitch), making this protein a cardiac-specific marker for myocardial damage. cTnI is not expressed in skeletal muscle at any developmental stage or in response to any pathological stimuli. Accordingly, elevations do not occur in plasma from patients with acute or chronic skeletal muscle disease unless acute myocardial injury is concomitant.

TnT (37,000 Da) is an essential component of the contractile apparatus that binds the troponin complex to the tropomyosin strand of the thin myosin filament of striated muscle. Antibodies that specifically recognize the amino acid sequence distinct for cTnT were developed and are the basis for quantitative measurement by immunoassay.

Both cTnT and cTnI rise above normal detectable limits about 3 h after symptoms begin. Depending on the method, cTnI may remain elevated for as long as 3–10 days and cTnT for as long as 2 weeks. Owing to these prolonged elevation periods, both cTnI and cTnT allow for diagnosis many days after MI has occurred. Problems may arise when trying to diagnose reinfarction, however, as serum levels may not have had adequate time to decline. cTnT has also been shown to be useful in following patients with unstable angina. As minor cell necrosis occurs, cTnT is released into the circulation. In patients with unstable angina, cTnT is either borderline or increased, and a substantial number of all those with elevated levels later develop an MI.

Although the release of the C–T–I troponin complex after myocardial injury is not fully characterized, several reports suggest that a large portion of TnI is liberated in the form of complex (predominantly with TnC) and only a small portion of TnI circulates in a free form. Few data are available on the release of TnT subunits into circulation after AMI. The release kinetics of troponin proteins are crucial especially when comparing troponin results of different commercial assays for these proteins. For the generation of monoclonal or polyclonal antibodies, highly purified proteins are usually used. However, TnI tightly interacts with the other two proteins of the troponin complex and separation of these proteins requires a high concentration of urea (6–8 mol L⁻¹). The exact structure of purified TnI in solution is different from that of TnI complexed with the other troponin proteins. Furthermore, TnC significantly alters the phosphorylation of TnI by different kinases. Finally, TnC and TnT affect the accessibility of the lysine residues of TnI to chemical modifications. All these factors indicate that the interaction of TnC and TnT with TnI will dramatically affect the overall structure of TnI. Consequently, antibodies raised against purified TnI may not be able to access epitopes on TnI that are modified in the whole troponin complex or in the binary complexes of TnI with TnC or TnT. Therefore, for developing a reliable TnI immunoassay, antibodies should be able to recognize both free TnI and TnI complexed with other troponin proteins.

### 8.7 Carbonic Anhydrase Isoenzyme III

Carbonic anhydrase (CA) exists in seven closely related isoforms in mammalian tissue. Two of the most abundant of these isoforms are CA I and CA II; both are found in erythrocytes with CA I in highest concentrations. CA II is also found in the cytosol of cells from many organs, including brain, liver, kidney, and lungs. Each of these isoforms shares approximately 55% amino acid sequence homology with CA III. This increases the importance of using a monoclonal detection antibody in any assay system used for CA III quantification.

CA III is a cytosolic protein (28,000 Da) found almost exclusively in type I (slow-twitch) skeletal muscle fibers and is a useful marker for many different types of muscle damage. Reports have stated that it is a more sensitive marker of muscle damage than CK. It can be used to monitor and diagnose patients with Duchenne muscular dystrophy (DMD) and may be used to monitor and diagnose patients with Duchenne muscular dystrophy (DMD).
muscular dystrophy and many other neuromuscular disorders. \(^{(44)}\) Recently, there has been increased interest in monitoring CA III along with myoglobin levels to evaluate patients for the possibility of AMI. In the event of skeletal muscle damage, myoglobin and CA III are released into the plasma by damaged cells in a fixed ratio (~3:1). \(^{(45)}\) This ratio is measurably increased in the case of an AMI. Because CA III is absent in cardiac muscle the ratio begins to rise as soon as myoglobin is released by the damaged cardiac cells. Recent studies have indicated that the use of the myoglobin/CA III ratio was more specific than CK-MB in diagnosing an AMI. \(^{(45,47)}\) This is due to the early release of myoglobin from injured myocardial cells. Peak serum levels are reached as fast as 1–4 h after AMI. Commercial diagnostic CA III assays are not yet available.

### 8.8 Human Heart Fatty Acid-binding Protein

Fatty acid-binding proteins (FABPs) are low-molecular weight (15,000 Da) cytosolic proteins which were first identified in the intestinal mucosa of rats. \(^{(48)}\) Since this discovery, several different forms have been found, including one which is abundant in the cytoplasm of human cardiomyocytes [human heart fatty acid-binding protein (HHFABP)]; HHFABP is also found in other body tissues. \(^{(49)}\) As quickly as 3 h following AMI, plasma concentrations of HHFABP have been shown to increase significantly. \(^{(50)}\) The initial problem with using HHFABP as a diagnostic indicator of AMI is that it is not specific to cardiac tissue. This problem may have been solved by recent work, which uses the ratio of myoglobin to HHFABP to distinguish between cardiac and skeletal muscle damage. \(^{(51)}\) The study indicates that the ratio of myoglobin to HHFABP following cardiac injury is significantly different than the ratio following skeletal muscle damage. Another problem with measuring HHFABP occurs in patients with chronic renal failure. HHFABP is cleared by the kidney and, as a result, patients with chronic renal failure can have plasma levels much higher (20–25-fold) than those in normal patients. \(^{(52)}\) Immunoassay methods are used for HHFABP determination.

### 8.9 Markers of Platelet Activation

Platelet activation is important in the mechanism of thrombus formation and the mechanism of ACS. Indicators of platelet activation such as platelet function assays or P-selectin measurement may help assess a patient’s tendency for intracoronary thrombosis. Platelet activation can result from contact with exposed collagen, thrombin and/or other agonists induced by plaque disruption. P-selectin is an adhesion molecule expressed on the surface of activated platelets. \(^{(53)}\) Expression of this protein is increased in patients with symptomatic coronary artery disease. \(^{(53)}\) Thus P-selectin may be a marker of activated or “angry” platelets that indicates their tendency to adhere to leukocytes causing accumulation and consequent thrombotic complications in the ischemic myocardium. \(^{(53)}\)

#### 8.10 Acute Phase Proteins

Increased levels of the acute phase proteins CRP and SAA are known to be nonspecific, but may have a role in identifying patients having unstable coronary plaques. Studies have investigated the use of CRP for predicting unfavorable outcome and impairment of left ventricular function resulting from acute cardiac necrosis or previous MI. \(^{(54)}\) The increase in acute phase proteins may indicate plaque disruption that causes release of cytokines from activated monocytes and macrophages at the disrupted site. \(^{(55)}\) Among other systemic effects, cytokines including interleukin-6 promote hepatic synthesis of the acute phase proteins. In this way, patients having unstable coronary artery disease who are at increased risk have abnormal circulating concentrations of acute phase proteins. \(^{(56,57)}\) A possible component of the observed association between acute phase proteins and increased risk is that these proteins may reflect infectious disease affecting the coronary vessels. \(^{(58)}\) In any case, aspirin or other nonsteroidal anti-inflammatory agents may reduce risk in coronary artery disease patients presumably by inhibiting the inflammatory process. \(^{(54)}\)

### 8.11 Markers of Thrombosis

Thrombus formation is fundamental to blockage of the infarct related artery. Therefore, markers of thrombosis, including soluble fibrin and fibrin degradation products, may also reveal a recent thrombotic process or risk of an impending event. Although not sensitive or specific enough to diagnose MI, soluble fibrin and cross-linked fibrin degradation are increased in patients who are at higher risk for complications. \(^{(59)}\) Physiologically, these markers are thought to indicate increased fibrinolysis prior to development of MI. \(^{(59)}\)

### 8.12 Markers of Early Myocardial Ischemia

A marker that is indicative of myocardial ischemia occurring prior to frank necrosis would be helpful for locating a patient’s position on the ACS continuum. Glycogen phosphorylase b is a key enzyme of glycogenolysis. It has three major isoenzymes: BB (brain and heart), MM (muscle), and LL (liver). GPBB is the predominant in the heart and has been found to be a sensitive indicator of myocardial injury. \(^{(60)}\) GPBB appears to increase upon ischemia without necrosis and may represent a...
marker of ischemia rather than necrosis.\(^{[61]}\) GPBB release is thought to be linked to the sudden burst of glycolysis which occurs in the injured myocardium following acute MI. A rise in GPBB levels can be detected as early as 3–6 h after the onset of symptoms. In a recent study, Rabitzsch et al. were able to develop an immunoenzymometric assay to measure GPBB.\(^{[61]}\) In testing patients during the first 4 h after the onset of symptoms, they reported GPBB to be more sensitive than CK, CK-MB mass, myoglobin, and cTnT. Research on GPBB as a biochemical marker for MI is still ongoing but preliminary results are encouraging.

Taken together, the markers of plaque rupture (CRP and SAA), indicators of intracoronary thrombosis (P-selectin and soluble fibrin), myocardial ischemia (GPBB), and markers of necrosis could be combined with clinical indicators, ECG, echocardiogram, and imaging studies to form an integrated combined model for optimum assessment of patient risk.

### 9 APPLICATIONS FOR CLINICAL MEASUREMENTS

#### 9.1 Diagnosis of Myocardial Infarction

Retrospective confirmation of MI is the classical role for biochemical markers of myocyte damage. Compared with CK-MB, troponin measurements offer substantial advantages to the detection of myocardial injury with respect to sensitivity and specificity. Feng et al. reported cTnI to be the most sensitive analyte in a swine model with induced severe coronary artery stenosis.\(^{[62]}\) Electron microscopy showed frequent TnI release during early stage myocardial ischemia and even from reversibly damaged myocardium.\(^{[63]}\)

The release kinetics of TnT and I are similar; both are released within 4–12 h after myocardial necrosis, with a peak value 12–48 h from symptom onset, affected by the duration of ischemia and reperfusion.\(^{[63,64]}\)

Because of the known delay in release, troponins are not generally considered early markers of MI.\(^{[65–68]}\) For greatest clinical sensitivity, serial sampling is recommended at least 12 h after onset of pain. Furthermore, troponin elevations due to minor myocardial necrosis, but with MI ruled out by WHO criteria, have been viewed as FP affecting diagnostic specificity.\(^{[69]}\) However, even in the absence of typical ST-segment changes or clinical symptoms, troponins can reliably diagnose acute MI. Patients with elevated troponin levels on admission are more likely to experience complications during follow-up.\(^{[67,70]}\) Comparison of TnT and I showed similar clinical sensitivity even when used with different cutoffs;\(^{[71]}\) therefore, both have equal potential to rule out MI within an acceptable time interval and allow early and cost-effective triage decisions in chest pain patients.\(^{[72]}\)

A temporal difference in clinical sensitivity between cTnI and CK-MB mass was demonstrated in several studies including a study based in the Emergency Medicine area.\(^{[71]}\) Use of a cTnI decision point of 1.5 ng mL\(^{-1}\) showed significantly lower clinical sensitivity compared with CK-MB mass at both 2 h ($P = 0.0001$) and 6 h ($P = 0.00016$) after presentation. The use of a lower cutoff of 0.6 ng mL\(^{-1}\) also showed statistically significant differences between cTnI and CK-MB at 2 h ($P < 0.0238$) and 6 h ($P = 0.025$). In the 12–24 h time frame, the differences in comparative sensitivities did not achieve statistical significance. Clinical specificity for MI diagnosis exceeded 97% for cTnI in all time frames examined.\(^{[71]}\)

For diagnosis of MI, serial sampling is necessary unless results of the first measurement exceed the decision point. The data indicate that cTnI sampling to at least 12 h after onset of symptoms should be performed to optimize clinical sensitivity for MI diagnosis.

Recently, the specificity of TnT to myocardial damage has been questioned; however, clinical data from studies on TnT re-expression in regenerating human skeletal muscle confirm troponins as superior markers of myocardial injury.\(^{[73,74]}\) Various researchers suggest that TnT or I should replace CK-MB for detecting acute MI (Table 4).\(^{[63,65–68,71,75–87]}\)

A meta-analysis showed that cTnT had a clinical sensitivity of 98.2% (CI 97–99%) for diagnosis of MI 12 h following onset of symptoms.\(^{[22]}\) This clinical sensitivity was not significantly different from results for CK-MB mass. However clinical specificity for cTnT was 68.8% (CI 66–72%), which was significantly different from CK-MB mass ($P < 0.001$). The reason for this difference was the inclusion of patients with minor myocardial injury associated with unstable angina. These unstable angina patients had cTnT results that exceeded the decision limits examined in this analysis. As will be presented later, these positive cTnT results are important because they identify unstable angina patients at increased risk for adverse cardiac events. Also, since this meta-analysis was performed, even more cardiac-specific second- and third-generation versions of the cTnT assay have become available.\(^{[34]}\)

Utilization of cTnT for MI diagnosis with optimum sensitivity requires samples collected 8–12 h after onset of symptoms. Owing to cTnT’s elevation in minor myocardial injury, clinical specificity in some studies was not as high for cTnT as CK-MB. However, subsequent studies using short-term mortality as the outcome have shown that these positive results are meaningful for the identification of high-risk patients. Very myocardial-specific cTnT immunoassays are available.\(^{[34]}\)
BIOCHEMICAL MARKERS OF ACUTE CORONARY SYNDROMES

9.2 Reinfarction

The magnitude of infarcted tissue is an important determinant of early and late morbidity and mortality.\(^\text{88}\) Because early reinfarction increases the cumulative extent of injury, recurrent infarction is suggested to have deleterious effects on prognosis.\(^\text{88}\) However, determination of the frequency and severity of reinfarction as well as patients at particularly high risk has been difficult. Clinical criteria commonly used to identify recurrent MI (also known as infarction extension) include severe prolonged chest pain and new ST-T wave electrocardiographic changes. (T wave is a component of the ECG complex.) However, these criteria have low specificity for reinfarction and may reflect other conditions such as pericarditis. Based on ST-T wave changes, the apparent incidence rate of reinfarction was reported to be as high as 86%.\(^\text{89}\) However, the reported incidence rate is < 20% as judged from morphological criteria among the subgroup of patients who succumb early after infarction.\(^\text{89}\) Using biochemical markers, such as repetitive evaluation of plasma CK activity, the apparent rate of reinfarction ranged between 34 and 65%.\(^\text{89,90}\) Such estimates may have been falsely elevated by frequent contributions to plasma CK from noncardiac sources.

Marmor et al. characterized the frequency and nature of recurrent infarction prospectively in 200 AMI patients.\(^\text{93}\) In addition to clinical and electrocardiographic criteria, they evaluated serial changes in plasma CK-MB activity and plasma myoglobin concentrations in all patients and radioventriculograms in selected patients to delineate the incidence of early reinfarction and identify features of patients at high risk. Among the patients studied, the overall incidence of early recurrent infarction was 17%, based on confirmation of recurrence of plasma CK-MB and plasma myoglobin elevations after both had returned to baseline levels following the initial infarction. It was observed that recurrent infarction was often manifested by regional ventricular deterioration. Ventricular function, as assessed with radioventriculography, in patients who did not undergo reinfarction either remained the same or improved slightly during the hospital stay. Recurrent infarction was observed in 43% of patients with initial subendocardial MI compared with only 8% of those with a transmural MI.\(^\text{93}\) The authors observed close correlations between (1) the magnitude of peak CK associated with the initial infarction and peak CK after early recurrent infarction and (2) sites of electrocardiographic and radioventriculographic changes with each of the two episodes. Therefore, the initial site of coronary arterial obstruction may be involved in both episodes and transitory improvement of flow may leave some myocardium at risk for a second wave of necrosis in proportion to the extent of initially jeopardized tissue.

9.3 Perioperative Myocardial Infarction

MI is the most common cause of morbidity and mortality in patients who have had noncardiac surgery.\(^\text{94}\) In patients with perioperative MI, mortality ranges between 36 and 70%.\(^\text{95,96}\) However, it is difficult to detect perioperative cardiac damage, because most episodes of
myocardial ischemia occur without changes in the heart rate or blood pressure.\textsuperscript{(97)} Although CK-MB has been the marker of choice for diagnosis of MI, elevated CK-MB levels can sometimes occur after surgery in the absence of apparent cardiac injury.\textsuperscript{(98)} This is because small amounts of CK-MB exist in healthy skeletal muscle, and therefore such FP elevations have been attributed to skeletal muscle injury occurring during surgery.\textsuperscript{(99)}

Data from one study indicated that patients undergoing vascular ($n=96$) or spinal ($n=8$) surgery had serial measurements of cTnI that were accurate in detecting perioperative MI or excluding the diagnosis.\textsuperscript{(100)} There was concordance between the development of abnormalities in segmental wall motion, as detected by echocardiography, and elevations in cTnI in 107 of the 108 patients included in this study. In contrast, CK-MB was elevated in 19\% of patients without perioperative cardiac injury, including eight of the 12 patients undergoing spinal surgery. FP elevations of CK-MB were more common than TP elevations among patients undergoing vascular surgery. Many cases of perioperative elevations of CK-MB are suggested to result from skeletal muscle rather than a cardiac injury. Since elevations of cTnI persist for 5–7 days after MI, the use of this marker to diagnose perioperative MI may demand one of two diagnostic strategies: (1) to measure cTnI only if MI is suspected and CK-MB levels are elevated, or (2) to obtain a preoperative cTnI value for comparison with postoperative values.

### 9.4 Reperfusion Assessment

The Thrombolysis in Myocardial Infarction (TIMI) study group has established a grading scale for the extent of patency: TIMI 0, no antegrade flow beyond the point of occlusion; TIMI 1, penetration without perfusion; TIMI 2, partial perfusion; and TIMI 3, complete perfusion.\textsuperscript{(101)} The TIMI grading scale is the “gold standard” in characterizing the success of biochemical markers and other indicators of coronary artery reperfusion status. The ability to evaluate intravenous thrombolytic therapy is important, with successful reperfusion defined as the establishment of full antegrade flow through the infarcted artery (TIMI grade 3 flow).\textsuperscript{(102)} Although coronary angiography is the gold standard for assessing patency, occlusion or reocclusion, this invasive procedure has risks that limit its routine use in all patients receiving thrombolytic therapy.\textsuperscript{(103)} Cardiac markers present a noninvasive tool to assess reperfusion. However, for reliable prediction of reperfusion, serial testing of cardiac markers to identify the initial rate of increase or the time to peak is needed.

Myoglobin shows an early and rapid increase after successful reperfusion compared with nonperfused patients. Abe et al. showed that the rate of increase of myoglobin (9.7-fold) is higher than that for total CK (2.8-fold) in the reperfused group of patients within 26 min of commencing thrombolysis.\textsuperscript{(104)} An approach that combined myoglobin, CK-MB, and clinical indicators has demonstrated success in assessing successful thrombolysis.

TnT has characteristic biphasic release kinetics: an early peak containing the cytosolic form which is affected by the washout after reperfusion and a later peak containing the bound form which is not affected by reperfusion. One study showed that the probability of reperfusion is >95\% when the ratio of peak cytosolic cTnT to the concentration at 38 h is >1.42 or the ratio of cTnT concentration at 14 to 38 h is >1.09.\textsuperscript{(105)}

In successfully reperfused AMI patients, cTnI increased 30, 60, and 90 min following thrombolytic therapy compared with the baseline and this increase was significant compared with nonperfused patients.\textsuperscript{(106)} Preliminary studies suggest that the calculation of the relative index of reperfusion at 90 min after thrombolytic therapy (cTnI at 90 min divided by cTnI at 0 min baseline) showed ~80\% sensitivity for detection of reperfusion.\textsuperscript{(106)}

### 9.5 Risk Stratification/Therapeutic Intervention

Risk stratification of ACS patients based on cardiac markers is an area of great potential. Also, recent studies suggest that cTnT and cTnI may be useful for therapy selection or guidance of intervention.\textsuperscript{(107,108)}

cTnI was measured at enrollment for 1404 patients enrolled in the TIMI IIb study using the Stratus method.\textsuperscript{(70)} The TIMI IIb population represented the unstable angina/non-Q-wave MI part of the ACS spectrum. Of this total population, 845 patients presented >6 h after onset of clinical symptoms, and were the focus of much of the analysis. The cTnI decision point used in this study was 0.4 ng mL$^{-1}$, the minimum detectable concentration of the assay. This study showed that for each increase of 1.0 ng mL$^{-1}$ in cTnI, there was a significant increase in risk of 42-day mortality after correction for baseline variables of age and ST-segment depression.\textsuperscript{(70)} Overall conclusions noted that a single cTnI measurement at enrollment was an independent risk factor for 42-day mortality and that the timing of cTnI measurement was critical. It is of note that there was no significant difference in mortality risk between patients with undetectable values, i.e. <0.4 ng mL$^{-1}$ and those with values between 0.4 and 1.0 ng mL$^{-1}$.\textsuperscript{(70)} An important finding was that among patients presenting >6 h after onset of symptoms, TnI was prognostic when the CK-MB mass was within the reference interval. This is presumably because CK-MB has insufficient sensitivity and specificity for microinfarction.\textsuperscript{(109)}

cTnT was examined at enrollment in a GUSTO (global use of strategies to open occluded coronary arteries)
Iiia sub-study that included 801 ACS patients using a primary end-point of 30-day mortality.\(^{(110)}\) It is of note that these patients represent a relatively high risk subset of the ACS continuum, as about 90% had MI within 18 h of enrollment.\(^{(110)}\) In these patients, cTnT measurement at a median of 178 min after onset of symptoms was an independent risk factor demonstrating a larger contribution than either ECG category or CK-MB mass. Further, this study used logistic regression analysis to demonstrate that after adjustment for ECG category and baseline CK-MB mass concentration, cTnT made a highly significant contribution for prediction of 30-day mortality \((P = 0.027)\). However, after adjustment for cTnT and ECG category, CK-MB did not add significantly to the ability of the model for predicting 30-day mortality \((P = 0.717)\). Hence CK-MB mass is not useful for risk stratification when cTnT measurements are available,\(^{(111)}\) as was found for cTnI in the TIMI IIIb study.\(^{(70)}\)

The contribution of later cTnT measurements, at 8 and 16 h after presentation, for improving the ability of predicting 30-day and 1-year mortality in the GUSTO Iiia population was reported.\(^{(112)}\) As shown in Table 5, the 8-h cTnT measurement added significantly to a logistic regression model for predicting 1-year mortality \((P = 0.0015)\). The 16-h cTnT measurement significantly improved the predictive ability of the model for both 30-day \((P = 0.0382)\) and 1-year mortality \((P = 0.0004)\). Only age and ST-segment elevation were stronger predictors of 30-day or 1-year mortality than cTnT measurement. The data in Table 4 also indicate that it is not necessary to collect both 8- and 16-h samples, as they do not add significant information to the predictive ability of cTnT. This study showed that serial sampling at the baseline and then at 8 or preferably 16 h is useful for evaluating the risk of serious cardiac events.\(^{(112)}\)

The GUSTO Iiia cohort was also used to compare the performance of baseline measurements of cTnT and cTnI for predicting risk of 30-day mortality.\(^{(113)}\) Both the cTnT and cTnI measurements were quantitative and were considered continuous variables in a combined logistic regression analysis in which 30-day mortality was the outcome. Table 6 shows that when each variable was considered alone, cTnT showed the highest significance for predicting 30-day mortality in this patient group. Further, combined logistic regression models were constructed to assess the relative contribution of cTnT, cTnI, and ECG for predicting 30-day cardiac death. When cTnI was added to a model developed with the ECG category and cTnT, the model’s predictive ability was not improved significantly (Table 6). However, when cTnI was added to a model containing ECG category and cTnI, there was a significant improvement in the model’s ability to predict 30-day mortality \((P = 0.045)\). When ECG category was added to a model combining cTnT and cTnI, it added the most information \((P = 0.019)\). It is of note that preliminary analysis indicates that after adding the 8- or 16-h samples there was no difference between the ability of cTnT and cTnI to predict 30-day mortality (data not shown).

A meta-analysis comparing risk stratification using cTnT and cTnI was conducted for studies having specimens collected within 12–24 h of presentation or chest pain, focusing on the unstable angina patients.\(^{(114)}\) As indicated in Table 7, this meta-analysis revealed no significant difference between cTnT and cTnI for predicting nonfatal MI and death at a median of 30 days for cTnT and a median of 42 days for cTnI.\(^{(114)}\) Risk of nonfatal MI and mortality in the 30 days following the index event was also assessed for cTnT and

cTnI in 773 acute chest pain patients, with measurements performed using POC devices from Roche Diagnostics and Spectral Diagnostics, respectively. Patients with ST-segment elevation were excluded from the study and sampling was performed at presentation and at ≥6 h after onset of symptoms. This study showed that the cTnT device was positive in 94% of the MI patients and the cTnI device was positive in 100% of patients. The risk of nonfatal MI or cardiac death in patients with negative test results was extremely low, as only 1.1% of the negative cTnI patients and 0.3% of the cTnT patients had presentations of patients having cTnT levels below a cutoff of <0.1 µg L⁻¹, short-term treatment showed no significant effect in decreasing the incidence of death and/or MI. However, in patients having levels of cTnT ≥ 0.1 µg L⁻¹, differences in the incidence of death and/or MI were significant as the event rate was 6.0% in the placebo group versus 2.5% in short-term treatment patients (P < 0.05). With long-term treatment with low molecular weight heparin the results were more dramatic. In patients having cTnT ≥ 0.1 µg L⁻¹, death and/or MI occurred at a rate in the placebo group nearly double that in the group receiving low molecular weight heparin (14.2 vs 7.4%; P < 0.01). On the other hand, cTnT levels < 0.1 µg L⁻¹ identified a low-risk group in whom death and MI showed no difference between the treated and placebo groups. This study indicated that elevated cTnT concentrations could potentially identify patients who would benefit from long-term treatment with low molecular weight heparin.

An important focus in cardiovascular therapeutics has been the development of agents that are antagonists for the platelet glycoprotein (GP) Ib/IIa receptor. These agents are important because conformational changes in the GP Ib/IIa receptor is the final step in platelet activation. The idea behind blockage of this receptor is to prevent platelets from becoming “angry” and contributing to the potential of thrombosis. The CAPTURE study included unstable angina patients who were randomized to receive either a GP Ib/IIa receptor inhibitor or a placebo. Prior to randomization, cTnT was measured in the patients and the subjects were classified as either positive or negative. In the 24–36 h after receiving either GP Ib/IIa inhibitor or placebo, cardiac catheterization was performed with angioplasty if necessary. The patients for whom the cTnT was negative showed a low incidence of death or MI while awaiting cardiac catheterization. Likewise, the cTnT positive patients who received the GP Ib/IIa inhibitor had a similarly low rate of death or MI. However, the patients receiving placebo who were cTnT positive had a significantly higher event rate of 4.1% compared with the cTnT group who received the platelet inhibitor (P = 0.03). Thus, in the CAPTURE trial cTnT measurements identified a group that benefited from administration of the GP Ib/IIa inhibitor. cTnT measurement may help focus this treatment in ACS patients.

### 9.5.1 Guidance of Therapy

There is strong evidence that TnT and TnI are indicators of increased risk in ACS patients and efforts have begun to examine if therapeutic intervention can reduce this risk. These activities are confluent with efforts in the therapeutics industry because drugs for ACS patients are frequently expensive, and definitive benefit is difficult to demonstrate. Although administration to all patients may be untenable based on costs, strategies using biochemical markers to identify patients at increased risk and who would benefit from therapies is being investigated. To gain insight into the future role of cardiac markers, and also other in vitro diagnostics, it is important to monitor the direction and evidence base of therapeutics and therapeutic trials. Two examples of the potential role for cardiac markers in the guidance of intervention are presented below.

The FRISC study examined whether TnT concentrations could be useful for identifying patients with unstable coronary artery disease who might benefit from therapeutic intervention. This issue was investigated by measuring cTnT levels in serum from 971 patients who received either placebo or low molecular weight heparin in short-term (6-day) or long-term (5-week) regimens. Among patients having cTnT levels below a cutoff of <0.1 µg L⁻¹, short-term treatment showed no significant effect in decreasing the incidence of death and/or MI. However, in patients having levels of cTnT ≥ 0.1 µg L⁻¹, differences in the incidence of death and/or MI were significant as the event rate was 6.0% in the placebo group versus 2.5% in short-term treatment patients (P < 0.05). With long-term treatment with low molecular weight heparin the results were more dramatic. In patients having cTnT ≥ 0.1 µg L⁻¹, death and/or MI occurred at a rate in the placebo group nearly double that in the group receiving low molecular weight heparin (14.2 vs 7.4%; P < 0.01). On the other hand, cTnT levels < 0.1 µg L⁻¹ identified a low-risk group in whom death and MI showed no difference between the treated and placebo groups. This study indicated that elevated cTnT concentrations could potentially identify patients who would benefit from long-term treatment with low molecular weight heparin.

### 9.6 Infarct Sizing

Infarct size correlates closely with mortality and also other prognostic indexes such as cardiac failure, ventricular function, and arrhythmia. Infarct size can be determined by electrocardiography, echocardiography, left ventriculography, and radionuclide methods or with cardiac markers. Although the ECG is convenient for estimating infarct size clinically, the estimation of infarct size...
from the ECG at the very early stage of MI is unreliable because ST-segment elevation and Q-wave amplitudes change spontaneously within 24 h of the onset of AMI and change rapidly after reperfusion.\(^{118}\)

Infarct size can be estimated by measuring myocardial proteins released from the injured myocardium. CK and CK-MB have been used for infarct sizing,\(^ {88}\) but they are not suitable for early estimation of infarct size because a period of 1–6 days is needed. On the other hand, myoglobin appears in the blood after infarction much earlier than CK owing to its low molecular weight. Serial measurements of myoglobin can be used for early estimation of infarct size. However, size from total myoglobin may be overestimated in patients with severe renal dysfunction, because myoglobin is rapidly excreted in urine and is not specific to the myocardium. The infarct size estimated from total myoglobin may be overestimated in patients receiving intramuscular injection, or those with shock, trauma, alcoholism, or muscle disorder. CK-MB, which has a better cardio-specificity than myoglobin, may be more suitable for estimating infarct size in patients with skeletal muscle damage. Infarct sizing can be estimated by plotting the release of a cardiac marker against time after the onset of chest pain and calculating the area under the curve. Calculation of infarct size using cardiac markers has correlated fairly well with estimates of necrotic zones made on cardiac tissue at autopsy.\(^ {119}\) Myocardial extension following an initial infarct reduces regional blood flow and delays the appearance of cardiac markers in blood, therefore affecting the use of cardiac markers for infarct sizing.

### 10 ECONOMIC ISSUES IN CARDIAC MARKERS

#### 10.1 Is Rapid Testing Necessary?

The need for rapid testing must be evaluated within the context of the role of biochemical markers in the management of patients with suspected ACS. Although ST-segment elevation is suggested for identifying patients

<table>
<thead>
<tr>
<th>Table 8 Recommendations for markers in the triage of chest pain patients</th>
</tr>
</thead>
<tbody>
<tr>
<td>Recommendation</td>
</tr>
<tr>
<td>---</td>
</tr>
<tr>
<td>1. Members of the EDs, divisions of cardiology, hospital administrations, and clinical laboratories should work collectively to develop an accelerated protocol for the use of biochemical markers in the evaluation of patients with possible ACS. For simplicity, this protocol should apply to either the facilitated diagnosis or the rule-out of AMI in the ED or to routine diagnosis from other areas of the hospital, should a patient develop symptoms consistent with ACSs while hospitalized.</td>
</tr>
<tr>
<td>2. For routine clinical practice, blood collections should be referenced relative to the time of presentation to the ED and (when available) the reported time of chest pain onset.</td>
</tr>
<tr>
<td>3. Two biochemical markers should be used for routine AMI diagnosis: an early marker (reliably increased in blood within 6 h after onset of symptoms) and a definitive marker (increased in blood after 6–9 h, but has high sensitivity and specificity for myocardial injury, remaining abnormal for several days after onset).</td>
</tr>
<tr>
<td>4. In patients with a diagnostic ECG, on presentation (ST-segment elevations, presence of Q-waves or left bundle branch block in two or more contiguous leads), the diagnosis of AMI can be made and acute treatment initiated without results of acute cardiac marker testing. In AMI patients with diagnostic ECGs, biochemical marker testing at a reduced frequency of blood collection (e.g. twice per day) is valuable for confirmation of diagnosis, to qualitatively estimate the size of the infarction, and to detect the presence of complications such as reinfarction.</td>
</tr>
<tr>
<td>5. For detection of AMI by enzyme or protein markers, in the absence of definitive ECGs, the following sampling frequency is recommended:</td>

(×) indicates optional determinations.

6. For those EDs in which patients’ triage decisions are not made within the first few hours after ED presentation, the use of an early marker such as myoglobin may be unnecessary. In this case, only one definitive marker such as cardiac troponin is needed. The frequency of blood collection should also be reduced. | Class I |
with AMI with a relatively high degree of specificity, the rate of misdiagnosis of AMI was found to be 20–24% even when strict clinical criteria and ECG are used to select for thrombolysis.\(^\text{120,121}\) Therefore, there is a role for cardiac markers in patients who have a conclusive ECG diagnosis of AMI, whether they receive thrombolytic therapy or not, for audit and clinical quality monitoring. Even in patients presenting with ST-segment elevation on ECG, measurement of cardiac troponins (cTnT or cTnI) allows a further risk stratification.\(^\text{67,70,110}\)

Recent technological advances in assay development have allowed short TATs and rapid results. The rationale behind rapid testing is the provision of a rapid accurate biochemical test result. Therefore, the evidence of rapid testing requires a number of questions to be answered. This area is best described by Collinson\(^\text{122}\) with the following four questions.

10.1.1 Is Rapid Biochemical Diagnosis Possible?

Rapid rule-in and rule-out of AMI using biochemical markers can be achieved by serial measurement of CK,\(^\text{123,124}\) and CK-MB alone or with myoglobin.\(^\text{125}\) In addition to their role in diagnosing AMI, cardiac troponins have additional value in prognostic risk stratification. The presence of detectable cTnT on admission in patients who receive thrombolysis is associated with an adverse prognosis\(^\text{7}\text{0,110}\) and failure to achieve TIMI III flow on postthrombolysis angioplasty.\(^\text{126}\) Such groups may benefit from primary angioplasty or aggressive thrombolytic treatment. The presence of cardiac troponin identifies a subgroup of unstable angina patients who will respond to low molecular weight heparin and GP IIb/IIIa antagonists. Several ongoing clinical trials are investigating the use of biochemical markers to guide therapy.

10.1.2 Is Rapid Biochemical Diagnosis Clinically Relevant?

Rapid diagnosis has a direct impact on patient management. Rapid diagnostic algorithm using 8-h CK measurement combined with calculation of rate of change was shown to reduce median Critical Care Unit stay by 1 day.\(^\text{127}\) Rapid diagnosis can be used for early rule-out of AMI in the ED, allowing safe and early discharge, minimizing inappropriate admissions and misdiagnosis rate,\(^\text{128}\) and reducing the length of hospital stay. Overall, rapid testing can result in considerable clinical benefit.

10.1.3 How Can Rapid Biochemical Testing be Delivered Accurately and Effectively?

There is a need for analytically accurate technology that can provide a rapid TAT. The laboratory can shorten TAT by the use of pneumatic tube sample delivery systems, fast analyzers, and electronic data systems. The limitation is therefore the sample processing time. Serum can be ready within 30 min at best, as the sample is allowed to clot before processing. Faster TAT can be achieved with plasma or whole blood. The alternative is the use of POC testing either by replicating the laboratory analyzers at the bedside or by using innovative technologies such as immuno-chromatographic devices, gold-labeled optically read immunoassay (GLORIA) and the use of whole-blood single or multiple marker assays. POC testing must be simple, robust, and analytically accurate. No prospective studies have been published where POC testing was used exclusively for management.

### Table 9 Recommendations for markers in ACS

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Strength/Consensus</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Two decision limits are needed for the optimum use of sensitive and specific cardiac markers such as cTnT or cTnI. A low abnormal value establishes the first presence of true myocardial injury, and a higher value is suggestive of injury to the extent that it qualifies as AMI, as defined previously by WHO.</td>
<td>Class I</td>
</tr>
<tr>
<td>2. Chest pain patients with laboratory results for cTnT and cTnI between the upper limit of the reference interval and the decision limit for AMI should be labeled as having “myocardial injury”. These patients should be admitted and acutely treated to reduce the risks associated with this injury.</td>
<td>Class I</td>
</tr>
<tr>
<td>3. The WHO definition of AMI should be expanded to include the use of serial biochemical markers and not be limited to enzyme changes. It should be emphasized that rule-out of AMI cannot be made on the basis of data from a single blood collection. However, when very specific cardiac markers are used, the presence of an abnormal concentration from a single specimen can be highly diagnostic of myocardial injury.</td>
<td>Class I</td>
</tr>
<tr>
<td>4. At this time, there are no data available to recommend the use of cardiac markers such as cTnT or cTnI for screening asymptomatic patients for the presence of ACSs. The likelihood of detecting silent ischemia is extremely low and cannot justify the costs of screening programs. Additionally, there is no evidence that cardiac marker analysis of blood following stress testing can indicate the presence of coronary artery disease.</td>
<td>Class III (for use of cardiac markers for screening)</td>
</tr>
</tbody>
</table>
10.1.4 Are the Cost Economics of Rapid Testing Justified?

Cost economic analysis of rapid rule-out protocols shows significant cost reductions compared with conventional approaches. Rapid diagnosis is effective and cost effective only within the context of data-driven decision-making protocols. POC testing for cardiac markers has a definitive role in management when a very short TAT is required such as in the ED. If the laboratory TAT exceeds 25% of the decision time, then rapid testing will be required. For therapeutic decisions to be made, only rapid testing will be able to satisfy the TAT requirement.

10.2 Triage Strategies

In the ED, little impartial evidence is available to differentiate patients with coronary artery diseases from those presenting with other causes of chest pain. Therefore, the assessment of symptomatic patients presenting to the ED is a challenging task. To determine the probability that a particular patient having an acute ischemic coronary syndrome, ED clinicians rely on the patient’s description of the chest discomfort, the presence or absence of nausea, vomiting, or diaphoresis, and the presence of risk factors for coronary artery disease.

Gibler et al. introduced a model that routinely incorporates serial testing for CK-MB on presentation to the ED and 3, 6, and 9 h later with continuous 12-lead ECGs/serial ST-segment trend monitoring for 9 h. Such a model was suggested to be effective for evaluating low- to moderate-risk patients with possible acute ischemic coronary syndrome in the ED. The cost effectiveness of this approach compared with standards in hospital evaluation warrants further assessment, as others have argued that widespread adoption of the chest pain ED concept may not be cost-effective.

<tbody>
<tr>
<td>1. For assessment of reperfusion status following thrombolytic therapy, at least two blood samples are collected and marker concentration compared: time = 0, defined as just before initiation of therapy, and time = 1, defined as 90 min after the start. From these values, the determination of the (a) slope value [(marker_{t=90} - marker_{t=0})/90 min]; (b) absolute value of marker_{t=90}, in minutes; or (c) the ratio of marker_{t=90}/marker_{t=0} can be used as the discriminating factor between successful and unsuccessful reperfusion. However, monitoring with biochemical marker strategies has not been successful in distinguishing between TIMI grade 3 and TIMI grade 2 flow patients, rendering the utility of these measurements clinically problematic for determining complete reperfusion.</td>
<td>Class II</td>
</tr>
<tr>
<td>2. cTnT or cTnI should be used for the detection of perioperative AMI in patients undergoing noncardiac surgical procedures. The same AMI decision limit should be used.</td>
<td>Class I</td>
</tr>
<tr>
<td>3. Cardiac markers should not be routinely used for infarct sizing because the existing markers are inaccurate in the presence of spontaneous, pharmacological, or surgical reperfusion.</td>
<td>Class III (for use of markers in infarct sizing)</td>
</tr>
<tr>
<td>4. Early in the process, manufacturers should seek assistance and provide support to professional organizations, such as the AACC or IFCC to develop committees for the standardization of new analytes. These organizations will determine the need for analyte standardization based on the potential clinical importance of the marker and gather the necessary scientific expertise for the formation of a standardization committee.</td>
<td>Class I</td>
</tr>
<tr>
<td>5. Reference intervals are established for each marker on a population of healthy individuals, using the 97.5 percentile (one-tail) of results. Separate cutoff concentrations for results indicative of AMI are also necessary for all cardiac markers. Standardized ROC curves should be used to establish AMI decision limits, using carefully selected and diagnosed populations.</td>
<td>Class I</td>
</tr>
<tr>
<td>6. For research studies involving the kinetics of release and appearance of new biochemical markers, the time course of release and appearance in blood must be defined relative to the onset of clinical symptoms. The diagnostic accuracy of these new markers may be compromised if the diagnosis of AMI for study patients is based on standard enzyme markers that themselves have sensitivity and/or specificity limitations (e.g. total CK and CK-MB). Therefore AMI diagnosis should be defined by WHO criteria, but with the substitution of “unequivocal serial changes of cTnT or cTnI” as the principal biochemical marker, in place of the current WHO criteria of “unequivocal serial enzyme changes”.</td>
<td>Class I</td>
</tr>
</tbody>
</table>

10.3 Cost of Patient Hospitalization

Despite major progress in managing coronary artery disease, approximately half a million individuals die each year from its complications in the USA alone. This reality has urged efforts to diagnose AMI quickly in the ED. Tests used in the ED to distinguish between chest pain of ischemic origin and that of benign causes are often inconclusive, thus leaving a large group of patients with low but important risk of poor outcome. A risk-avoidance strategy has been adopted by many clinicians leading to conservative admission of over 3 million chest pain patients in the USA alone, costing 3–4 billion dollars yearly for those who were found to be disease free. However, AMI remains one of the leading causes of malpractice suits against physicians. In addition, the traditional models of health care delivery “inpatients” versus “outpatients” may not match patient needs. This has inspired the development of alternative health care delivery models such as chest pain units\textsuperscript{130} and accelerated diagnostic protocols (ADPs).

One study evaluated whether the use of an ED-based ADP can reduce hospital admission rate, total cost, and length of stay for patients needing admission for evaluation of chest pain.\textsuperscript{131} This randomized trial included 165 patients and compared admission rate, total cost, and length of stay for patients treated using ADP versus inpatient controls. Control patients were admitted to the telemetry unit on the internal medicine service for standard management including two sets of cardiac marker studies, two ECGs, and 24 h of cardiac and clinical monitoring. Until a diagnostic end-point was met (positive CK-MB result, recurrent chest pain, or ECG findings consistent with myocardial ischemia) or the protocol was completed, the ADP patients received (1) 12 h of rhythm monitoring, (2) CK-MB level measurements at 0, 4, 8, and 12 h, (3) ECG at 0, 6, and 12 h, (4) clinical examination and review of test results at 0, 6, and 12 h or for any change in condition, (5) aspirin, (6) 2 L of oxygen by nasal cannula, and (7) intravenous line. During the first 12 h, patients with any positive test results were hospitalized, and patients with suggestive findings for myocardial ischemia were also hospitalized. If all clinical findings were negative, patients were subjected to ECG exercise stress test and classified as ADP discharges (negative stress test) or ADP admissions (positive ECG stress test). This study concluded that the hospital admission rate for ADP versus control patients was ~45% versus 100% ($P < 0.001$). The mean total cost per patient for ADP versus control patients was $1528 versus $2095 ($P < 0.001$). The mean length of stay was 33.1 h for ADP patients versus 44.8 h for controls ($P < 0.1$). In this trial, ADP strategy saved $567 in total hospital costs per patient treated. Therefore, use of ED-based ADP was shown to reduce hospitalization rates, length of stay, and total cost for evaluating low-risk patients with chest pain for possible AMI or acute cardiac ischemia. Locating space for ADPs in or near the ED is advantageous because it will reduce inpatient bed requirements while allowing optimum use of the high fixed costs of ED maintenance. Only hospitals already at full capacity may consider initiating a separate unit with new staff, equipment, and

construction. There is a consensus that ED-based ADPs can maintain quality care in a cost-cutting environment. Maximum benefits of ADPs may be achieved via further research to determine optimum settings, patient selection, and protocol design.

11 RECOMMENDATIONS FOR THE USE OF CARDIAC MARKERS IN CORONARY ARTERY DISEASE

The National Academy of Clinical Biochemistry Standards of Laboratory Practice assembled a committee to write recommendations on the use of cardiac markers in coronary artery diseases. The recommendations were divided into four areas: the use of markers in the triage of patients with chest pain, ACS, clinical applications other than AMI and research, and assay platforms and markers of AMI.

11.1 Definition of Classification Scheme

The classes are defined as follows:

- Class I: a recommendation for which there is evidence and/or general agreement.
- Class II: a recommendation for which there is conflicting evidence and/or a divergence of opinion about its usefulness/efficacy, but where the weight of evidence/opinion is in its favor.
- Class III: a recommendation for which there is evidence and/or general agreement that a procedure is not useful or effective.

Details of the recommendations are given in Tables 8–11.

ABBREVIATIONS AND ACRONYMS

ACS | Acute Coronary Syndrome
ADP | Accelerated Diagnostic Protocol
AK | Adenylate Kinase
AMI | Acute Myocardial Infarction
ATPase | Adenosine Triphosphatase
CA | Carbonic Anhydrase
CI | Confidence Interval
CK | Creatine Kinase
CPEC | Chest Pain Evaluation Center
CRP | C-reactive Protein
cTnI | Cardiac Troponin I
cTnT | Cardiac Troponin T
CV | Coefficient of Variation
ECG | Electrocardiogram
ED | Emergency Department
ELISA | Enzyme-linked Immunosorbent Assay
FABP | Fatty Acid-binding Protein
FN | False Negative
FP | False Positive
GLORIA | Gold-labeled Optically Read Immunoassay
GP | Glycoprotein
GPBB | Glycogen Phosphorylase-BB
GUSTO | Global Use of Strategies to Open Occluded Coronary Arteries
HHFABP | Human Heart Fatty Acid-binding Protein
LD | Lactate Dehydrogenase
MI | Myocardial Infarction
NADPH | Nicotinamide Adenine Dinucleotide Phosphate (Reduced Form)
NHAAP | National Heart Attack Alert Program
NIH | National Institutes of Health
NPV | Negative Predictive Value
POC | Point-of-care
PPV | Positive Predictive Value
ROC | Receiver Operator Characteristic
SAA | Serum Amyloid A
TAT | Turnaround Time
TIMI | Thrombolysis in Myocardial Infarction
TN | True Negative
TnC | Troponin C
TnI | Troponin I
TnT | Troponin T
TP | True Positive
UV | Ultraviolet
WHO | World Health Organization

BIOCHEMICAL MARKERS OF ACUTE CORONARY SYNDROMES

This paper presents the use of biosensor devices for bioanalytical purposes. In contrast to common analytical tools using sophisticated and bulky devices, biosensors should be able to perform measurements in untreated samples in a simple and inexpensive manner. As a model creating biosensors serves nature which produces a variety of selective molecules during evolution that can be used in technical sensor devices. Combining such natural molecules with methods from microelectronics, mass fabrication of laboratories on chip seems feasible. Emerging markets for such tools can be seen in medicine, drug screening and biotechnology.

After explaining the principles of biosensors different transducing methods are explained showing advantages and disadvantages for creating biosensors. The greatest emphasis is laid on electrochemical and optical principles which exhibit an overwhelming experience and the largest impact on future developments. Despite such developments, acoustic and calorimetric transducers are also explained. As biological sensing agents enzymes, antibodies and DNA are described with appropriate immobilizing procedures.

Additionally, new aspects for creating a laboratory-on-chip using microanalytical systems (µTAS) including microfluidics and actuator modules are given for creating sensing systems for metabolic parameters and also cell-based and affinity-based systems for screening purposes. The purpose of this section is to give an overview and to explain the present possibilities for creating biosensor systems and ends up with an outlook in the near analytical future for new sophisticated and miniaturized analytical systems.

1 INTRODUCTION

Biosensors are fascinating analytical tools that attracted great attention in the past, promising to revolutionize the whole analytical and diagnostic world, causing the prediction of a huge market in the near future. However, these general predictions have not yet been fulfilled due to technical and production problems and for market reasons. Unquestionably, the use of biological highly selective and sensitive sensing parts in the vicinity of a transducer, which is the original definition of a biosensor, still creates a lot of interest. Nature has developed similar systems during evolution; all biological systems inherently not in thermodynamic equilibrium need a variety of sensing components to maintain control and stability which might serve as a model for complex multibiosensor systems for industrial applications. However, despite this challenging analytical approach until now the only types of biosensors with market success are single-shot glucose sensors and biosensor modules for clinical analyzers.

In the 1960s biosensors were fabricated conventionally with macroscopic membranes and transducers, gluing wires together and dipping them in membrane solutions. For small-scale production, as required for clinical analyzers, this was a realistic approach. It is interesting to note that even though biosensors have a long history very few are able to perform measurements in undiluted biological fluids for long-term applications. Changing the daily optical-based glucose check for diabetes patients to electrochemical sensors, with millions of sensors sold per year, the method of production also changed, and screen printed sensors conquered the market.

However, for further diagnostic and analytical procedures such as continuous metabolic monitoring, high throughout screening (HTS), DNA, immunological diagnostics and point of care management, new ways for
biosensor design and fabrication have to be developed. Multiple biosensor arrays able to perform measurements over an extended period in undiluted biological media with the possibility of mass production have to be developed.

Due to the problems related to biosensors in principle, finding appropriate immobilizing strategies, overcoming transducer-related problems and finding the right production method, only a few activities take place in research and development dealing with all the problems. Up to now, no device is commercially available for use in a daily routine.

Some activities are related to silicon-based technology that is not necessarily the best for the apparent user problems. A combination of microelectronic-compatible immobilizing strategies with robust electrochemical microtransducers and proper analyte diffusion and enzymatic pathway control leads to an interesting candidate for creating multianalyte-multitarget biosensor arrays. This is described in more detail in the following sections.

2 PRINCIPLES OF BIOSENSORS

Small, integrated and reliable sensing elements are necessary for metabolic monitoring, decentralized laboratories, and for drug screening. Such devices can be realized by "sensors", elements receiving physico-chemical information and transforming such information into an electric signal. To measure metabolic parameters selectively "biosensors" are required. A schematic drawing of a biosensor is given in Figure 1.

A biosensor is a device incorporating a biological sensing agent either intimately connected to or integrated into a transducer using the old definition of tuner and is capable of performing a variety of clinical analyses in principle.\(^2\) The most advanced biosensors use enzymes with the glucose sensor as the main representative. The commonly used biochemical systems utilize the enzyme glucose oxidase (GOx) and measure the product \(H_2O_2\) electrochemically. In this case, GOx converts the substrate glucose and oxygen to gluconolactone, \(H_2O_2\) and generated heat \(\Delta H\) (Equation 1).

\[
\text{Glucose} + \text{O}_2 \rightarrow \text{gluconolactone} + \text{H}_2\text{O}_2 + \Delta H \quad (1)
\]

Many different enzymes commercially available can be used for biosensors in principle. Also affinity-based devices with immobilized antibodies or receptors can be used to get highly sensitive biosensors.\(^{15}\) Many biosensing structures are available ranging from enzymes, antibodies, receptors, tissue slices and whole cells.\(^{15,13}\) Recent developments incorporate organ or tissue slices or whole cells on a transducing element to get a more biologically based environment, thus performing reliable measurements.\(^4\)

There are also several transducing principles available: The systems best investigated use electrochemical sensors but there are also acoustic devices, calorimetric and optical sensors available. To obtain a general overview of biosensors there are some excellent reviews available.\(^{2,3,5–7}\)

3 CLINICAL DIAGNOSTICS

Diagnostics has a high priority in medical practice, and the microelectronic revolution has played an important part in establishing radiological diagnostic tools. However, to obtain a deeper insight into metabolic functions of the body, clinically important metabolic parameters have to be measured continuously in different body compartments. Until now, this task could only be done with certain restrictions using radioactive tracers or nuclear magnetic resonance (NMR).\(^8\) Such technologies are not able to perform continuous measurements of metabolic parameters required for monitoring in the intensive care unit or multianalyte-multitarget detection for rapid screening in pharmacology in the near future.

Metabolic parameters are accessible externally only by standard clinical laboratory methods. In recent years, analytical laboratory instrumentation has become highly sophisticated, with the ability to routinely process hundreds to thousands of samples a day. However, modern clinical and pharmacological practice urgently requires miniaturized monitoring tools and point-of-care systems that cannot be realized by standard clinical laboratory methods.\(^9–12\) Therefore, miniaturized and integrated biosensor systems are required consisting of glucose-, lactate-, urea-, creatinine-, immuno-, cell-based and DNA-sensor arrays, which suggests the use of microsystem production technology.\(^1,13,14\) The devices of greatest interest to be used for whole blood testing and monitoring in the intensive care unit, for emergencies, for satellite laboratories and in new generations of analytical instruments analyze glucose which tops the list of analytes that clinicians would like to measure continuously in vivo.\(^15\) The discrete measurement of glucose for diabetics with a market volume of 3 x 10^9 US dollars in 1998 is of particular interest.\(^11\)
4 BIOSENSOR DEVICES

The ultimate goal in producing biosensor microsystems is the realization of a complete microanalysis system or laboratory-on-chip, and therefore new combinations and integration of technologies have to be applied. Microsystem technology with the claim of interdisciplinarity could be a good way to produce several thousands to millions of devices per year in typical production plants.

Different production technologies, such as silicon, thin-film and screen printing technologies, are available with different features and are well suited for different market sizes and customer needs (Table 1). Together with genetic engineering and material sciences, these technologies yield promising expectations of new routes to achieve broader use of biosensor systems.

For choosing the right production technology a user- and market-driven approach is recommended: application areas are clinical, pharmacological and biological fields as well as process control with several new and rapidly growing markets, e.g. point of care measurements and pharmaceutical screening topics. These cases require decentralized portable analytical devices for unskilled personnel with high reproducibility and reliability at low production costs. If there is no need for extreme miniaturization, and no advantage comes from a special technology (e.g. Si-monolithic integration), a low-tech production such as screen-printing or polymer-based technologies is recommended.

An often-cited argument is the benefit of using standard silicon technology. However, there are not too many biosensor applications with a high market volume to make use of the benefits of silicon technology, and also very few biosensors need the integration of microelectronic components in the vicinity of the transducer. Therefore, already marketed microelectronic biosensors make use of thin-film and screen printing technology!

The successful introduction of new technologies in emerging markets can be seen in the recent rapid progress of microelectronics. The tremendous advance of this technology was inherently connected to the completely new production methods allowing the reproducible production of a large quantity of identical products and devices. The benefits of the mentioned technology such as cheap mass production, high reproducibility and capability of integration of various functions on a miniaturized scale raise the expectation of success for microelectronic sensors. Up to now this expectation has not been entirely fulfilled; primarily physical sensors such as pressure, acceleration sensors or charge coupled device (CCD) imaging chips have been successfully introduced into the market.

Microelectronics plays an important part in medical imaging techniques, data acquisition and processing but is less important in medical sensors. This will probably change by the introduction of new ways of designing analytical systems with microsystems. Additional to the required miniaturization and production of the transducer, sensor performance is of importance. It should be stable for a sufficiently long time, exhibiting full response without pretreatment of samples. Thus, designers of a biosensor microsystem have also to overcome the problems of choosing the right transducers, optimizing them and immobilizing biological sensing agents onto them on a large-scale level. In the realization of biosensor microsystems, the transducing element as the base device is of primary importance.

4.1 Optical Microtransducers for Biosensors

Optical sensors are interesting analytic tools capable of performing a variety of different analyses where most of the work has been done on measuring pH, \( P_{O_2} \) and \( P_{CO_2} \). The biosensing devices are mainly focusing on affinity principles such as e.g. antibody–antigen reactions and are based on surface plasmon resonance (SPR), grating couplers or interferometers. It seems possible to obtain stable and highly sensitive devices based on these principles, and further investigations can lead to miniaturized sensor modules at reduced cost, size and complexity. In diagnostics and rapid screening environments label-free in situ monitoring of molecular binding events are of outstanding interest.

The surface plasmon principle was commercialized as one of the first direct biosensor devices.\(^{(22)}\) A SPR occurs when surface plasmon waves are excited at a thin metal/liquid interface, which is the sensor surface. A polarized light beam is directed at, and reflected from, the side of the surface not in contact with the sample. The SPR causes a reduction in the reflected light intensity at a specific combination of angle and wavelength. The intensity of reflected light exhibits a pronounced maximum at a distinct angle, which is a function of the refractive index of the metal/liquid interface that is seen by the evanescent incident wave. Molecular binding to the sensor surface causes changes in the refractive index close to the surface that can be detected as changes in the SPR signal. The principles of the optical set-up are seen in Figure 2; the reflected light beam I is changed during a surface binding event to beam II.

However, the detection of a direct binding assay is limited to a mass coverage of 10 pg mm\(^{-2}\) in the case of SPR and is approximately 10 times better for interferometers.\(^{(20,22)}\) Not only sensitivity is a limiting factor, but also unwanted unspecific adsorption of proteins can reduce selectivity.

Integrated optical devices combine microelectronic production technology with the inherent advantages of optical sensing. Many of these developments are at an early state of research but a variety of optical biosensors can be realized in principle. Apart from the described problems, direct binding approaches suffer from the drawback that a highly paralleled set-up is not easily possible. Instead, optical methods using labeled biorecognition molecules and chemiluminescence can be applied.\(^{(23)}\) Not only sensitivity is a limiting factor, but also unwanted unspecific adsorption of proteins can reduce selectivity.

Many of these developments are at an early state of research but a variety of optical biosensors can be realized in principle. Apart from the described problems, direct binding approaches suffer from the drawback that a highly paralleled set-up is not easily possible. Instead, optical methods using labeled biorecognition molecules and chemiluminescence can be applied.\(^{(23)}\) Not only sensitivity is a limiting factor, but also unwanted unspecific adsorption of proteins can reduce selectivity.

Integrated optical devices combine microelectronic production technology with the inherent advantages of optical sensing. Many of these developments are at an early state of research but a variety of optical biosensors can be realized in principle. Apart from the described problems, direct binding approaches suffer from the drawback that a highly paralleled set-up is not easily possible. Instead, optical methods using labeled biorecognition molecules and chemiluminescence can be applied.\(^{(23)}\) Not only sensitivity is a limiting factor, but also unwanted unspecific adsorption of proteins can reduce selectivity.

4.2 Biosensors Based on Acoustic Transducers

The principle of acoustic devices is the change of mass on a surface during an adsorption or binding event. Three types of transducer mechanisms are used: Bulk Acoustic Wave (BAW) using shear oscillations of piezoelectric crystals, Surface Acoustic Wave (SAW) using wavemode propagation, and Lamb Waves (LW) which are flexure acoustic waves of a free standing piezoelectric layer. Such detection methods are very sensitive, and submonolayers can be detected that are routinely used with BAW devices to control the evaporation process in microelectronic technology.

Many applications have been reported using piezoelectric sensors for gaseous components. Acoustic transducers such as piezoelectric microbalance and SAW devices that are in an early state of research have been developed primarily for volatile analytes and recently for affinity reactions.\(^{(27)}\) The use of acoustic devices in liquids has long been inhibited by the problem of the high energy losses at the solid/liquid interface.

The commonly used devices utilize commercially available and robust BAW transducers. However, the sensitivity of acoustic devices is directly proportional to frequency and inversely proportional to the sensor area giving SAW devices an advantage.\(^{(7)}\) A SAW device consists of a piezoelectric substrate and a pair of interdigitated electrodes that act as sensing and receiving transducers (Figure 3). By applying high frequency electrical waves on the electrodes the electric field generates acoustic waves at the piezoelectric surface (Rayleigh waves). The distribution of a SAW is a function of the surface conditions such as mass loading or changing the elastic properties of the material. All changes due to adsorbed species will be measured with high sensitivity. Therefore selectivity means a problem for all acoustic devices, because unwanted adsorption of interfering species can be measured with high sensitivity.
substances is detected in all cases, e.g. humidity is a general problem for gas sensing.

Another source of problems with acoustic devices for assaying binding events is the liquid analyte phase. All variations in density and viscosity of the liquid influence the acoustic signal. Additionally, if a binding event changes the volume of the used biological substance, e.g. receptors, the buoyancy force will also change. If used in biological samples the unwanted adsorption of proteins or tissue compartments remains a severe problem. In any case, SAW sensors are candidates for proper test systems with specified constant analyte matrix.

Recently encouraging results for immuno-sensing were presented using low-loss SAW filters based on horizontal shear waves with lithium tantalate.\(^{(26)}\) Such devices exhibit a typical attenuation of 4 dB in water. Using an appropriate polyamide insulation with subsequent immobilization of dextrans an immunosensor could be produced with sufficient sensitivity and low unspecific response.

### 4.3 Biosensors Based on Calorimetric Transducers

Calorimetric biosensors are based on the detection of the heat of biological reactions caused by changes in enthalpy. Such a microcalorimetric sensing principle is very versatile because of the exothermic nature of nearly all enzymatic reactions and was introduced in conventionally constructed devices very early.\(^{(29,30)}\) If a chemical reaction is occurring in an adiabatically isolated mass, which is defined as a calorimeter, then the temperature of the mass will change according to Equation (2)

\[
\Delta T = \frac{\Delta Q}{MC_c}
\]

where \(\Delta T\) is the temperature change, \(\Delta Q\) the energy difference, \(M\) the total mass of the calorimeter and \(C_c\) the total thermal capacity of the calorimeter.

Conventional calorimetric biosensors with thermistors as transducers were invented early by proposing a thermal biosensor in a flow stream.\(^{(31)}\) So far the design of enzyme thermistors does not entirely match the market demand, but it seems well-suited for special applications utilizing discrete thermistors with immobilized enzymes or with separate enzyme columns.\(^{(30–32)}\) A drawback for performing calorimetric measurements in a conventional way is the lack of well-matched thermistors. Recently a thin-film thermistor based on amorphous germanium has closed this gap.\(^{(33)}\)

As an alternative, transducer thermopiles are well suited for performing differential measurements due to their underlying physical principle to measure temperature differences directly with high common-mode rejection.\(^{(34)}\) Using conventional wire-based thermocouples, there are some difficulties related to size, sensitivity, and mechanical stability. If silicon technology is involved all thermal sensors suffer from the high thermal conductivity of silicon dramatically decreasing their sensitivity.\(^{(35)}\)

By use of micromachining and integrated silicon technology powerful thermal biosensors can be realized. Using a thermopile integrated on a thin micromachined silicon membrane reduces thermal losses due to the substrate and allows excellent performance to be achieved.\(^{(34)}\)

To realize glucose-, urea- and penicillin sensors in a flow injection mode appropriate enzymes can be immobilized though the measuring range is very limited in all reported cases due to enzyme kinetics, and a more sophisticated set-up is required.\(^{(34)}\) For clinical applications the calorimetric method was extended for whole blood and in vivo measurements of glucose.\(^{(36,37)}\)

With microelectronic and micromachining tools, an array of thermistors covered by different enzymes can be easily produced leading to a multianalyte detection using the same transducing principle.\(^{(38)}\) Such technologies allow the sample volume to be reduced to 1 µL and the response time is well below 1 min. A schematic drawing of a multianalyte device is shown in Figure 4.

### 4.4 Electrochemical Biosensors

Electrochemical biosensors are most commonly used and based on well-known transducing principles that have been investigated intensively during the last decades. Electrochemical transducers can be divided into conductometric, potentiometric, and amperometric measuring principles.

#### 4.4.1 Conductometric Biosensors

A simple transducing principle is the measurement of impedance between planar electrodes changed by altering

![Figure 4 Integrated multienzyme thermistor device for the simultaneous assay of more than one analyte.](image-url)
the ionic content of the measuring system. If biological sensing elements are immobilized on such electrodes, biosensors can be realized using changes of the conductivity in the electrolyte solution caused by biological reactions or changes of the double layer capacitance by binding (affinity) reactions of the biological molecules immobilized on the electrode surface.

Planar interdigitated electrodes for impedimetric measurements can be produced by means of microelectronic technology (Figure 5). Although this measuring principle has been known for a long time further investigations are required to understand the transduction principle in more detail for biosensing. One advantage of this general transducing principle is the possibility of creating biosensing arrays.

Using highly miniaturized microelectrode arrays with interdistances in the 0.5 µm range affinity-based sensors can be realized to measure DNA hybridization. Encouraging results recommend such a device for more investigations to get closer to practical applications and commercialization.

4.4.2 Potentiometric Transducers

Potentiometric measurements involve the determination of the electrical potential between two electrodes at zero current flow. A reference electrode has to establish a constant potential independent of the electrolyte used which is not easily performed even with standard electrochemical systems. For miniaturized reference electrodes various constructions were investigated using different electrolyte chambers and porous plugs.

The working electrode has to respond directly to the analyte to be measured, mostly pH and ion concentration. Such devices respond to changes in the analyte ion activity by varying the electrical potential described by the Nernst Equation (3)

\[ E = E_o + \frac{RT}{zF} \ln a_1 \]

where \( E \) is the electromotive force, \( E_o \) the standard potential, \( R \) the gas constant, \( T \) the absolute temperature, \( z \) the exchanged electrons, \( F \) the Faraday constant and \( a_1 \) the activity of the species to be detected.

The first representative of a potentiometric sensor was the pH-glass electrode invented in 1906. Many ion-selective electrodes have been developed including more recently those based on neutral carrier membranes and the microelectronic ion selective field effect transistor (ISFET). Such an ISFET was originally used for pH detection but by casting with ion-selective membranes a lot of different ion-selective sensors can be obtained. Even a multiparameter electrolyte sensitive chip for clinical applications was developed. To obtain a microelectronic biosensor, a biological substance has to be immobilized onto the gate insulator of the ISFET.

The enzyme-containing field effect transistor (ENFET), is fabricated from an ISFET by casting a thin membrane containing the enzyme over an ion-selective membrane or an inorganic gate insulator. The underlying mechanism of ISFETs and the enzyme reactions are described in Turner et al., Hall, Scheller and Schubert and Lundström et al. A schematic set-up of an ENFET is shown in Figure 6 where the enzyme is immobilized in a thin membrane over an ion-selective membrane.

Local changes in the ion activity due to substrate conversion by the immobilized enzymes have been measured using pH, fluoride-sensitive field effect transistors or ammonia-sensitive field effect transistors. Immunosensing with the field effect transistor gate by the
direct detection of protein interaction has been described in the literature but direct detection of protein interaction with a pH-sensitive gate is limited by fundamental principles.\(^{(53)}\)

Commercialization of ISFET devices is limited due to several problems. First, the ISFET device itself reveals some problems: drift, sensitivity to ambient light, dependence on buffer capacity in the sample, encapsulation problems and sensitivity against contamination.\(^{(50)}\) The provisionally used gate materials for pH sensing, \(\text{SiO}_2\) and \(\text{Si}_3\text{N}_4\), exhibit a large drift and do not show the expected Nernstian response.\(^{(47,54)}\) Special gate materials such as \(\text{Al}_2\text{O}_3\) or \(\text{Ta}_2\text{O}_5\) result in an enhancement of slope and better drift properties, though with large differences in sensor performance reported.\(^{(55)}\) Additionally, the described special gate materials cannot be deposited in a standard complementary metal oxide semiconductor production plant.\(^{(49,56)}\)

Furthermore there are severe problems related to packaging, and an attempt was made to create suspended gates and sophisticated assembling procedures.\(^{(50,57)}\) Another drawback for ISFET devices is the relatively large area required for a device leading to increased costs. These problems are extended for biosensor devices because of the additional integration of a biological component on a planar device surface.

A fundamental limitation of typical ENFET is the biochemical principle used as the sensing reactions have to be a pH change or a variation of surface potential. In the case of glucose sensing a double enzyme system has to be used to get optimum sensitivity which increases the complexity of the system.\(^{(58)}\)

Different approaches were reported for enzyme immobilization and membrane deposition including drop-on techniques, ink-jet printing, and photolithographically patterned enzyme membranes.\(^{(51,59–62)}\)

Integrated multibiосensors based on ISFET can be produced by using a photosensitive polymer that incorporates the enzyme and that is spun onto the gate (Figure 7).\(^{(7)}\) However, the reported measuring range for glucose is rather weak and some cross-sensitivities due to problems regarded with buffer type and capacity are also reported. Another approach immobilizes enzymes by printing with an ink jet nozzle.\(^{(60)}\) A photopolymer was used to create enzyme solution pools and to protect the ISFET surface from mechanical damage. To these pools, about 100 drops of enzyme solution were added. Using such a method, an integrated glucose and urea sensor can be produced. Again, however, the measuring range is very limited.

A possibility to extend the linear range and to perform measurements in whole blood is to use a further diffusion-limited membrane.\(^{(63)}\) Unfortunately, such an approach slows down the sensor response; nevertheless, measurements in serum and biological fluid are possible.

As nearly all ENFET approaches lead to insufficient or unsatisfactory sensor performance, no ISFET-based biosensor has been fully commercialized for wider applications to date. Although the ISFET exhibits a long history, a lot of work still remains to be done.

Another approach is the use of the potentiometric principle with planar thin film electrodes on a separate chip but in close vicinity to a field effect transistor input amplifier. Glucose and urea chips are now on the market commercialized by the i-stat company. These sensors are based on ion sensitive electrodes placed on silicon wafers. The problems of stability are circumvented by a simple on-chip calibration procedure and by the use of such microelectronic electrodes as disposable single-shot probes.\(^{(64,65)}\)

4.4.3 Amperometric Biosensors

The most frequently used biosensors are based on amperometric principles, using the Faraday current derived from a redox reaction at an electrode. A distinct voltage controlled by a potentiostat is applied between a working electrode and the electrolyte where all redox species are electrochemically converted. This results in a stationary current following Equation (4) in the case of a diffusion-controlled measurement of redox species.

\[
I = \frac{nFADc_o}{d}
\]

where \(I\) is the diffusion limited current, \(n\) the exchanged electrons per reaction, \(F\) the Faraday equivalent, \(A\) the electrode area, \(D\) the diffusion constant of the analyte, \(c_o\) the analyte concentration and \(d\) the thickness of the diffusion layer.

In contrast to the potentiometric principle where nearly no transport of analyte to the sensor occurs,
the amperometric measurement requires the control of Faraday current at the electrodes and the diffusion of an analyte towards the electrode. This divides the problems of amperometric sensing devices in transducer- and membrane-related ones. Miniaturized enzymatic amperometric biosensors produced by means of thin and thick film technology have been investigated extensively in recent years.66–71 Electrochemical analysis using planar thin film metal electrodes as transducer can be done in vitro with high performance.72

At present, nearly all of the cited amperometric microelectronic sensors intended for long-term application are not able to work well in undiluted blood, and only a few conventional macroscopic sensor systems are able to measure glucose and lactate concentration in undiluted media for an extended period.73,74 Transducer- and biomembrane-related difficulties have to be overcome with electrochemical transducers for measurements in undiluted biological media:

4.4.3.1 Transducer The biosensor systems best investigated use H2O2 producing oxidases. The subsequent oxidation of H2O2 on the working electrodes at a potential of 400 mV to 650 mV versus an Ag/AgCl reference electrode serves as a transducing mechanism.

One of the problems with amperometric devices in biological samples is the degradation of electrochemical performance over time due to contamination of the electrode.75 Therefore surface modifications or special electrode materials, e.g. carbon, are needed and the electrodes have to be covered with functional membranes.76

Another problem is the unwanted oxidation of other substances such as paracetamol, ascorbic acid or uric acid. The erroneous readings deriving from these substances can be overcome by differential methods using an enzyme-covered electrode and a blank electrode. Such systems are able to compensate for electrochemical interference but cannot hinder fouling of the electrodes.77

A further method is the use of mediated devices allowing reduced working potentials down to +200 mV where the interfering substances are not oxidized.78 However, the drawback of mediator-based devices in long-term applications is the leakage of mediators.69 Mediated devices are an excellent way to overcome the problems mentioned for short-term measurements.

The first commercially available disposable electrochemical device for measuring glucose in whole blood was a mediated system produced by screen printing.79 Several companies are now following with similar approaches.80,81

For long-term operations, other approaches have to be used. One possibility is the direct “wiring” of the enzyme to the electrode. “Wiring” is accomplished by immobilizing the enzyme in an electron conducting redox hydrogel.82,83 The hydrogel, being water rich, is permeable to both analyte and product. It conducts electrons through collisions between its mobile chain segments, the electrons being transferred from redox segment to redox segment by self-exchange. Because the redox functions are chemically bound to the polymer, they are not leached by the fluid. The redox potential of the enzyme “wired” polymer is sufficiently reduced to avoid unwanted oxidation of interferents.84

Another approach to protect the Pt working electrodes against fouling and to prevent erroneous reading due to electrochemical interference, an electropolymerized semi-permeable membrane can be utilized, which can be done on a wafer level.85

The reported semi-permeable membrane consists of an electropolymerized dianaminobenzene polymerized in phosphate buffer (pH = 7). The polymerization was done by cycling the potential between 200 mV and 800 mV for a certain period. In principle, such an electrode modification hinders fouling in an excellent way.86

4.4.3.2 Biomembrane Membrane fouling caused by protein adsorption is another problem for all types of amperometric sensors that leads to a decrease in sensitivity. To overcome the described problems apart from the dilution method, the solution is to utilize complex membrane systems.74,77 In addition, problems to immobilize biological substances and to establish proper diffusion limitation have to be overcome. In the case of the cited mediated disposable glucose sensor screen printing of free enzymes and mediator was used. Due to the solubility of both substances only single shot applications can be performed. For long-term applications more sophisticated methods have to be used.

A further problem for biosensor microsystems is the immobilization procedure of biosensing structures, e.g. enzymes. Again different approaches were tried including drop-on techniques, ink-jet printing, spray techniques, electropolymerization, lift-off techniques, and photolithographically patterned enzyme membranes.66–71,87

A miniaturized planar amperometric glucose sensor can be placed on sapphire substrates to overcome problems with conducting silicon substrates. Thin film metal electrodes are covered with an enzyme layer patterned by a lift-off technique.71 This sensor exhibits a fast response time of 30 s but the linear measuring range is poor.

The continuous in vivo measurement of glucose by a sensor implanted in patients is of great importance. Such monitoring can lead to a better control of normoglycaemia, a better quality of life and a hypoglycemic alarm which is of outstanding importance.88 For in vivo measurements, another planar glucose biosensor with Pt electrodes on a silicon substrate was developed (Figure 8).72
The enzyme GOx was immobilized by the well-known glutaraldehyde–bovine serum albumin method and the complete sensor was covered subsequently by a polyurethane membrane. This silicon chip had to be sawed and assembled on a flexible carrier for application as an in vivo sensor and was successfully evaluated in rats. This sensor gives encouraging results in aqueous solutions and subcutaneous applications. Drawbacks of this device are the complicated mounting and difficult and cumbersome assembling procedures.

Another approach places the Pt electrodes directly on a flexible polymer carrier. The company Eli Lilly developed a three-electrode transducing system based on a polyimide carrier with electroadsorbed enzyme and a highly oxygen permeable membrane covering the sensor. Such a system was tested in vivo, and published results seem encouraging. Due to general problems with implanted sensors, company policies cancelled this project.

For microelectronic production and to obtain clinical reliable sensors the ultraviolet initiated free radical crosslinking of the polymer directly on the substrate is a great advantage by designing the physical-chemical properties of the membrane. An interesting development is the use of planar biosensors with immobilized enzymes incorporated in the photopatterned hydrogel poly(vinyl alcohol)-stilbene. This leads to a convenient production process compatible with microelectronic technology. Such sensor devices are encouraging and interesting showing the possibility for creating microelectronic amperometric biosensors but suffer from insufficient measuring range and are not tested in whole blood required for clinical applications.

A combination of different technologies such as electropolymerization and photopatternable enzyme membranes can lead to reliable sensor systems. An easy to handle thin film process was developed for immobilizing different H₂O₂ producing enzymes. The hydrogel layer, containing e.g. the enzyme GOx, can be patterned by photolithography and placed selectively on the individual working electrode. An uppermost photopatternable membrane was introduced containing the enzyme catalase decomposing excess H₂O₂ into O₂ and water in order to prevent the release of the cytotoxic agent H₂O₂ into the biological environment. This membrane also prevents electrode fouling by blood components because of the low protein deposition characteristics of poly(hydroxy methacrylate).

To increase the diffusion path and to separate the H₂O₂ source (GOx) and the H₂O₂ sink (catalase), an additional poly(hydroxy methacrylate) membrane was placed between the GOx and catalase membrane. A schematic drawing of this device is shown in Figure 9.

Multianalyte chips can be produced in this way using microelectronic technology. The sensors do not show any dependence on interferences. They exhibit extended linear ranges with high sensitivities and low residual currents. Due to the wafer processing a high reproducibility can be obtained. The thin hydrogel membranes exhibit a fast response time of 25 s to 98% equilibrated signal and a fast hydration time of several minutes. The sensor chips can be stored dry for at least 3 months at 4 °C without changes in performance. The long term operational stability in undiluted bovine serum spiked with analyte is more than 1 month at 37 °C for the lactate sensor.

This is an example that multienzyme sensor devices can be designed to obtain precise, reliable, integrated biosensors with extended measuring range for clinical applications.
use. They can be produced by means of micro-
electronic technology. Such multienzyme sensors were
accomplished by immobilizing different enzymes into
stacked membranes structured by photolithography.

This is an important step towards commercialization,
and an additional feature is the possibility of integrating
additional electrochemical sensors for measuring O₂, CO₂
and pH on one substrate. Such an integrated lab-on-
chip seems to be a realistic vision and can revolutionize
the point of care testing. Additionally the technology of
photopatterned multienzyme sensors can be used for the
creation of in vivo devices on a flexible polyimide strip
(Figure 10).\(^\text{92}\)

5 MICROANALYTIC SYSTEMS

The technology for integrating different biosensors on
a chip is the basis for the lab-on-chip, which requires
additional liquid handling and optionally active liquid
treatment. Different approaches for a microanalytic
system (µTAS) are published and are now an emerging
field of research.\(^\text{93,94}\)

For several reasons, most applications of chemo- and
biosensors require flow-through devices. They allow
analysis of different samples from multiple sources,
to get rid of flow sensitivities, to avoid sterilization
and biocompatibility problems, to enable recalibration,
or to design complete bioanalytical assays. A classic
approach for a flow-through device with sensors is the
clinical-chemical analyzer using photometric techniques
and a bulky fluid handling system.\(^\text{95}\) In order to reduce
system costs and allow miniaturization the classic optical
approach is successively replaced by solid-state devices.
In future, integration of the liquid handling environment
with sensor elements will reduce assembling effort, minimize internal analyte volumes, and allow sample
pretreatment and reagent addition.

5.1 Electrolyte Sensing Systems

ISFET-based systems were developed at different lab-
oratories using a planar or three-dimensional set-up.\(^\text{96-98}\)
Such systems equipped with micropumps and valves are
able to detect ions and other important chemical param-
eters (Figure 11). Microarrays for measuring pressure,
temperature, pH, O₂ and CO₂ were realized using sil-
icon technology and a hybrid set-up of the different
components.\(^\text{99,100}\)

Hybrid microflow injection analysis systems produced
in silicon technology using oxygen microelectrodes and
microcavities were presented, also optic-based microana-
lytical systems were achieved.\(^\text{101,102}\)

5.2 Sensing Systems for Metabolic Parameters

Multiple analyte biosensor arrays can also be realized
using thin film and silicon technology. The so-called con-
tainment technology was applied to immobilize enzymes
in three-dimensional cavities formed in silicon wafers
to get fully process compatible biosensor devices.\(^\text{103}\)
Such systems were developed and used for microdialysis
sampling in human serum.\(^\text{104,105}\)

Another approach combines the described biosensor
microsystems (section 3.4.3) with a low cost microfluidics
by utilizing printed circuit board (PCB) technology which
is capable of producing microsystems.\(^\text{106,107}\) The PCB for
the assembly of the thin film biosensor array comprises
conducting pads for the thin film device and the plug
connection to the potentiostat. Additionally a 5 × 1 mm²
gold counter electrode, drilled holes for liquid inlet and
outlet, and a photopatterned spacer made from the dry
film resist used for insulation are integrated onto the PCB
(Figures 12 and 13).

To meet the demands for multianalyte monitoring in
biotechnology where closed loop control of metabo-
lites is expected to increase fermentation reliability
and yield a glucose–lactate–glutamine–glutamate device
Figure 12 Photomicrograph illustrating the assembling of the thin film sensor array with the PCB. 1, Contact structure; 2, spacer; 3, counter electrode; 4, sensor array.

Figure 13 Schematic cross-section of a microflow system. 1, SiN_x insulation layer; 2, PCB; 3, inlet; 4, counter electrode; 5, outlet; 6, glass wafer; 7, individual enzyme sensors; 8, reference electrode; 9, spacer; 10, glue.

Monitoring the concentrations of these four substances simultaneously, without any reagent, and with no need for sample pretreatment was realized by Moser et al.\textsuperscript{[108]} Figure 14 shows the calibration graphs of such a device. The small apparatus effort needed for monitoring is very attractive.

Ex vivo blood monitoring experiments with human volunteers were performed by placing a device comprising two glucose and two lactate sensors into the sampling line of a double lumen catheter. Venous blood was continuously withdrawn and in line heparinized with a dilution of less than 5%.

These experiments are described in detail in Jobst et al.\textsuperscript{[109]} Before measurement the glucose/lactate device is one point calibrated with a protein-free buffer solution. The measured sensitivities are applied to the sensor currents of the experiments for calculation of glucose and lactate levels and show the time course of glucose and lactate levels of a combined intravenous and oral glucose tolerance test together with the reference values (Figures 15 and 16).

The good correspondence between sensor and laboratory results proves the effectiveness of the precalibration procedure and sensor stability. The results suggest that these devices can be used for short-term glucose/lactate monitoring, e.g. in the intensive care unit, the operating theater, in sports medicine and rehabilitation, and in diabetology.

An advanced lab-on-chip equipped with biosensors and microfluidics can also be performed. On-line buffering and reagent addition can be also done integrating a

Figure 14 Calibration graphs.

Figure 15 Glucose sensor reading (solid line) and reference values (crosses).
mixing coil of $170 \times 0.6 \times 0.1 \text{mm}^3 (=10.2 \mu \text{L})$ onto the PCB together with a further inlet hole. The entire processing was done with conventional PCB technology equipment. Assembling the thin film sensor array with this PCB similar to that shown in Figures 12 and 13 gives the analytical microflow system. The dimension of the flow chamber is $5 \times 1 \times 0.3 \text{mm}^3 (=1.5 \mu \text{L})$.

A sensor array comprising two lactate and two lactose sensors is assembled with a PCB comprising a mixing coil (Figure 17) for yogurt fermentation monitoring. The sample flow of $6 \mu \text{L min}^{-1}$ is on-line buffered and diluted with $100 \mu \text{L min}^{-1}$ of a phosphate-buffered saline pH 7.4 carrier solution. During yogurt fermentation, the pH of the sample changes drastically over several pH units. Reliable measurements with biosensors are not possible without sample pretreatment due to the pH sensitivity of the enzymes used. However, with an on-line buffering strategy, monitoring with biosensors can be done even in strongly changing matrices. Such strong changes in matrix composition occur during most bacterial and fungal fermentation.$^{(110)}$

**Figure 16** L-lactate sensor reading (solid line) and reference values (boxes).

**Figure 17** Schematic cross-section of the flow through device with integrated static mixer. 1, Dry film resist layers; 2, mixing coil; 3, reference electrode; 4, individual enzyme sensors; 5, outlet; 6, gold counter electrode.

**Figure 18** Calibration graph for AST and ALT assay.

Another application of such a lab-on-chip device is the reagent addition, demonstrated with an assay for the glutamate producing enzymes glutamic oxaloacetic transaminase (AST) and glutamic pyruvic transaminase (ALT).$^{(111)}$ A thin film biosensor array comprising two glutamate and two blank sensors is assembled with a PCB comprising a mixing coil (Figure 17). The sample containing the enzyme to be assayed and a reagent with the respective enzyme substrates are mixed in the mixing coil. After flow stop the increase in glutamate concentration is monitored by the difference signal from the glutamate and the blank sensors. The calibration graph of such a device for a AST and a ALT assay is shown in Figure 18.

Compared to conventional spectrophotometric assays for these enzymes, this assay offers the advantages of needing no enzymes to be added to the reagent and electrical readout that allows running this assay even in whole blood. Such an assay scheme with a bioanalytic microsystem can be applied to a variety of diagnostic important enzymes. Also attractive is the possibility to directly combine metabolite analysis, e.g. lactate and glucose, with enzyme assays in one device, giving a more versatile lab-on-chip.

The set-up of the whole device is performed using the HYMOS (HYbrid MOdular microSystem) approach which was reported in Urban.$^{(112)}$ This device consists of two components made by means of well established mass production technologies (thin film and PCB technology) and assembling of the parts is compatible to intensive care packaging techniques, so cost effective mass fabrication of this device seems realistic.

**5.3 Cell-based Systems**

Microphysiometry is the measurement of the metabolic activity of living cells in a miniaturized environment.
Considerable interest in such devices from the industry arises from their applicability for drug screening. Other applications are toxicity monitoring and cytotoxin response measurement of cancer cells. Future applications could be strain prescreening in biotechnology, rapid sterility tests, and HTS in combinatorial chemistry.

According to the different ways in which cells alter their environment, e.g. produce heat, acidification, oxygen consumption or metabolite production, various sensors have to be used to measure these complex metabolic activities. To get a deeper insight into the cell metabolism, different sensors were integrated into one small test chamber. Using microsystem technology even an entire fermenter can be realized.

For high throughput applications, e.g. drug screening, massive parallelization and therefore miniaturization is required. Different companies are now entering the market with microphysiometer arrays based on light-addressable potentiometric sensors for pH sensing. In addition, an electrode arrangement for amperometry can be realized in subnanoliter containments, and even single cell microphysiometry seems feasible with this method. In an optical low cost approach, an ultrathin pH responsive membrane is placed on replicated chirped grating couplers. A resolution of $10^{-4}$ pH units was achieved but miniaturization of such a type of optical device is limited.

Probing oxygen consumption or metabolite production gives additional or complementary information about the cell metabolism. In addition, the metabolic activity of single cells can be measured by means of microsystem technology.

The challenge of establishing hundreds or thousands of electrical contacts if such amperometrically transduced microphysiometers undergo massive parallelization can be satisfied by multiplexing the individual sensors by complementary metal oxide semiconductor components integrated on a silicon wafer.

A localized cocultivation of cells on a chip to get an artificial liver or diagnostic devices is also possible. Some even more exciting developments can be expected from this combination of biosciences and microsystem technology in the near future.

### 5.4 Affinity-based Systems

Among biosensor microsystems using chemosensors and enzymes, affinity-based arrays as immunoassays and DNA assays are emerging fields of biosensor microsystems. Microchip arrays for parallel binding and detection of DNA or proteins for drug discovery and different clinical microsystems are under development.

The most advanced system uses a DNA chip with up to 65,000 different exactly specified 20-mer polynucleotides immobilized on a silicon chip and an epifluoroscopic read out of fluorescence labeled probe nucleotides whereas point defects in DNA can be easily detected.

Other strategies immobilize DNA selectively on complementary metal oxide semiconductor biochips using electrochemical methods. Hybridization can be controlled electrostatically, the readout is performed using fluorophore labeled target DNA and a CCD camera. For arrays up to several hundred DNA spots this seems a feasible and the least expensive method for DNA screening.

### 6 CONCLUSIONS AND OUTLOOK

The enthusiasm and the high expectations in biosensor microsystems have not been fulfilled till now, and technological breakthroughs and further work are still needed to ultimately fulfil them. Up to now only the glucose sensor has been widely marketed and has conquered the market, otherwise only niche markets could be covered by microelectronic biosensor devices for decentralized clinical analyzers.

Increasing production volumes resulting in lower prices of devices will push the whole market and new technologies will open additional markets. The expectations of using small samples as well as small reagent volumes, minimization of time expenditure of skilled clinical staff, minimization of calibration fluids consumption and waste are still key advantages of such a microtechnology. Additionally performing highly parallel assays to process thousands of samples immediately will also push rapid drug screening.

Realizing highly reliable devices produced by the appropriate production technology means a breakthrough of microelectronic biosensor systems is still expected. For market driven applications such as HTS, gene-based analysis, and decentralized laboratories a distinct solution can still be expected in the near future.

### ABBREVIATIONS AND ACRONYMS

- ALT Glutamic Pyruvic Transaminase
- AST Glutamic Oxaloacetic Transaminase
- BAW Bulk Acoustic Wave
- CCD Charge Coupled Dence
- ENFET Enzyme-containing Field Effect Transistor
- GOx Glucose Oxidase
- HTS High Throughput Screening
- ISFET Ion Selective Field Effect Transistor
- LW Lamb Waves
- NMR Nuclear Magnetic Resonance
PCB Printed Circuit Board
SAW Surface Acoustic Wave
SPR Surface Plasmon Resonance

Capillary Electrophoresis in Clinical Chemistry

1 INTRODUCTION

CE is electrophoresis in capillary format. It is the most efficient and versatile separation technique nowadays for analysis of small and large molecules. Although many concepts of CE separation had been demonstrated in the 1960s, research on CE did not gain momentum until the early 1980s. The transformation of conventional electrophoresis to modern CE was facilitated by the production of inexpensive narrow-bore fused-silica capillary, and by the development of highly sensitive on-line detectors for microcolumn liquid chromatography (LC).

A CE instrument (Figure 1) usually consists of the following basic components: a high-voltage power supply (0–30 kV), a fused-silica (SiO₂) capillary, two electrodes, two buffer reservoirs, and an on-line detector. Sample injection is accomplished by temporarily replacing one of the buffer reservoirs with a sample vial. A desirable amount of sample can be introduced into the capillary by controlling either voltage or pressure.

CE analysis is usually very fast and efficient, uses little sample and reagents, and costs much less than chromatography or conventional electrophoresis. The unprecedented efficiency of CE is an inherent feature of the technique. Like that of LC, the separation efficiency of CE can be modeled by the Van Deemter equation, which relates the plate height, \( H \), to the velocity, \( v_x \), of the carrier fluid along the separation axis \( x \) (Equation 1).

\[
H = A + \frac{B}{v_x} + Cv_x
\]

where \( A, B, \) and \( C \) are constants. A lower value of \( H \) corresponds to a higher separation efficiency – when the plate height is reduced, more theoretical plates (\( N \)) can be packed into a given length (\( L \)) along the separation axis (Equation 2).

\[
N = \frac{L}{H}
\]

The resolution (\( R_s \)) of two components in a mixture is proportional to \( \sqrt{N} \) (Equation 3):

\[
R_s = \frac{\sqrt{N}}{4} \left( \frac{\alpha - 1}{\alpha} \right) \left( \frac{k_2^2}{1 + k_2^2} \right)
\]

Capillary electrophoresis (CE) is electrophoresis in capillary format. It is the most efficient and versatile separation technique nowadays for analysis of small and large molecules. Clinical chemistry is a science that applies the knowledge of chemistry to the understanding of the human in health and disease. Implementation of CE technique in clinical laboratories will enhance the capability of the current clinical diagnostic system, and improve the quality of clinical testing. Owing to the nature of clinical diagnostics, the adoption of CE methods in clinical laboratories has been slow. However, CE has begun to replace some older and antiquated methods in some pioneering clinical laboratories.
where $\alpha = \frac{k_2}{k_1}$ is the selectivity of two adjacent peaks 1 and 2; and $k_1$ and $k_2$ are the capacity factors of these peaks. In CE, because the separation is carried out in a single phase of uniformly flowing carrier fluid, two of the three terms in Equation 1 (the multiple-path term, $A$, and the mass-transfer term, $C_v$) that contribute to the plate height are eliminated. Therefore, the only source of band broadening under ideal condition is the longitudinal diffusion term, $B/v$. Typically, a CE separation invokes 50,000 to 500,000 theoretical plates, which is an order-of-magnitude better than the competing LC method.

CE is the fastest growing analytical technique in the 1990s. Although CE is still in its early stage of development, it has demonstrated tremendous potential for the analysis of a wide range of biologically active molecules. In this article, the focus will be on the applications of CE in routine hospital laboratories and in specialized clinical settings. It is not intended to be comprehensive of all published papers; a selection has been made of those that are significant to clinical diagnosis of diseases.

## 2 SEPARATION PRINCIPLE

### 2.1 Terminology

#### 2.1.1 Electrophoresis

Electrophoresis is defined as the migration of ions under the influence of an electric field. The force ($F_e = qE$) produced by the electrical field on an ion is directly proportional to its effective charge, $q$, and the electric field strength, $E$. The translational movement of the ion is opposed by a retarding frictional force ($F_f = f v_{ep}$) that is proportional to the velocity of the ion, $v_{ep}$, and the friction coefficient, $f$. The ion almost instantly reaches a steady-state velocity where the accelerating force equals the frictional force (Equation 4):

$$qE = f v_{ep}$$  \hspace{1cm} (4)

Rearranging Equation (4) yields Equation (5):

$$v_{ep} = \frac{q}{f} E = \mu_{ep} E$$  \hspace{1cm} (5)

where $\mu_{ep}$ is the electrophoretic mobility of the ion, a proportional constant between the velocity of the ion and the strength of the electric field. The electrophoretic mobility is directly proportional to the charge of the ion and inversely proportional to the friction coefficient.

The friction coefficient of the moving ion is related to the hydrodynamic radius of the ion, $r$, and the viscosity of the medium, $\eta$ (Equation 6):

$$f = 6\pi \eta r$$  \hspace{1cm} (6)

Because of $\mu_{ep} = q/f$, a larger hydrodynamic radius translates to a lower electrophoretic mobility.

#### 2.1.2 Electroosmosis

Electroosmosis refers to the movement of a buffer solution in a capillary under the influence of an electric field. The inner surface of a fused-silica capillary is covered with silanol (Si–OH) groups, which are ionized to SiO− at pH > 2. The negatively charged surface is counterbalanced by positive ions from the buffer, forming a so-called “electrical double layer”. Under the influence of an electric field, the positive ions in the diffuse part of the double layer migrate towards the cathode and in doing so they entrain water of hydration and cause electroosmotic flow (EOF). The equations of EOF are identical to those developed for electrophoresis, as the two phenomena are complementary. The electroosmotic velocity, $v_{eo}$, is defined by Equation (7):

$$v_{eo} = \mu_{eo} E$$  \hspace{1cm} (7)

where $\mu_{eo}$ is the electroosmotic mobility, a proportional constant between the velocity of the EOF and the strength of the electric field. Electroosmotic mobility is directly proportional to the dielectric constant of the medium, $\varepsilon$, and the zeta potential at the capillary-buffer interface, $\zeta$, and inversely proportional to the viscosity of the medium, $\eta$ (Equation 8):

$$\mu_{eo} = \frac{\varepsilon \zeta}{4\pi \eta}$$  \hspace{1cm} (8)

The zeta potential is largely dependent on the electrostatic nature of the inner surface of the capillary, and to a small extent on the ionic strength of the buffer. In a fused-silica capillary, electroosmosis is diminished...
at low pH because protons convert the charged SiO\(^-\) surface to SiOH, causing a decrease in zeta potential. Electroosmosis also decreases with increasing ionic strength owing to the collapse of the electrical double layer. Practically, EOF can be eliminated by derivatizing the silanol groups on the inner surface of a capillary with a polymer solution (e.g. polyacrylamide or methylcellulose).

2.1.3 Apparent Mobility

The apparent mobility of a solute, \(\mu_{\text{app}}\), is a vector sum of the electrophoretic mobility of the solute, \(\mu_{\text{ep}}\), and the electroosmotic mobility of the buffer, \(\mu_{\text{eo}}\) (Equation 9):

\[
\mu_{\text{app}} = \mu_{\text{ep}} + \mu_{\text{eo}} \tag{9}
\]

The apparent velocity of a solute, \(v_{\text{app}}\), is directly proportional to \(\mu_{\text{app}}\) and the strength of an electric field across the capillary, \(E\) (Equation 10):

\[
v_{\text{app}} = \mu_{\text{app}} E \tag{10}
\]
